The operator watches the 3 gradually getting larger while he counts. When he has counted 6 it also will read 6, but the next two figures, 5 3, are more than the divisor, so he goes on. The next count, 7, then necessarily agrees with the indication of the wheel which receives the carryings, and the operative wheels to the right show 1 as the temporary remainder, so the answer at present is 7 and 1 over. If a long decimal answer is required the figures are made to slide along the keys on the rows on which they find themselves, in this case two places at first and then one place at a time, and are pressed down, the fingers alternately and simultaneously rising and falling, while the operator counts and watches the wheel receiving the carryings, and thus each new figure of the quotient is found, the time necessary for a figure varying from two to five seconds according as it is low or high. This is the time I require after no regular practice. I expect a skilled operator would require but little more than half as much. It seems strange at first that the mere process of addition should, where necessary, lead to a long decimal quotient, but, as explained above, such a result must follow.

The gradual and irregular change of the wheel receiving the carryings until it agrees with the count, so as to give a figure of the quotient, also seems mysterious. The manufacturers do not think it necessary to explain to users why this is so, but they give the following somewhat wholesome advice. "Do not worry about why the above process brings the answer. It is simply an arbitrary rule by which any and all examples in division can be computed on the comptometer, and, once understood, is so simple that it cannot be forgotten. All there is to it is that you strike the divisor on the keys just as many times as indicated by the figure in the 'next place to the left in the register,' and then, if the remainder is larger than the divisor, strike the keys again once or more times until the remainder becomes smaller than the divisor."

There is no occasion for much worry any way, for the mystery may be explained quite easily. Let $na+r$ be the dividend and a the divisor: then n is the quotient and r is "over." What is done by the machine is to add $1-a$ n times, counting up to n. When this has been done the result will be $na+r+n(1-a)$ $= n$, and r is "over."

The operation described is quite simple, easy and quick where the divisor has two figures only, and is not inconvenient with as many as four, for then two fingers of each hand may be used and the keys struck without looking at them. When the divisor has more than four figures the process is modified in an ingenious way, but in such cases the comptometer is, in my opinion, definitely less convenient than any good arithmometer.

The comptometer is conveniently available for ordinary commercial operations, such as interest and discount, as well as for merely adding up accounts. In the ordinary machine with only decimal notation the last two columns must be retained for the pence, the next two for the shillings, leaving all the rest for the pounds. However, a special build is now promised with special shilling and pence columns, so that on this any number of money entries, taken in any order, may be very quickly added up. Nevertheless, the process of dividing by 12 or 20 on the decimal machine, for which it is necessary to strike the keys marked in black 8 and 8 or 1, as the case may be, is so rapid that the pence when added up become shillings and pence on the register in a moment, and the shillings, which must be added after the pence, become pounds and shillings in even less time, and the pounds, shillings and pence so obtained are in their proper places. The comptometer arranged for British currency would, however, be the more convenient where the adding up of accounts is mostly wanted, but it does not seem as if it would meet every case that will arise. For instance, in a large retail business the number of entries to be checked of this type, $23\frac{3}{4}$ yards at 7*s.* $9\frac{1}{2}$*d.* a yard, is so great that in one case that I know of a special branch of the office is devoted to this work alone. The cost of this branch amounts to 1000*l.* a year, and yet, partly in consequence of the amazing quickness of the clerks, but chiefly because of our hopeless non-decimal system, it is not possible with much advantage to employ mechanical means of calculation to reduce this tax upon the business. Now with a decimal money system the multiplication by 23·75 in a machine would be direct and simple enough, but I do not see how this could be *directly* effected upon the British currency comptometer. I do not see how multiplication or division by numbers of several digits can be advantageously carried out.

As a last example of the way in which ingenuity has been exercised in finding a way of making this adding machine perform other operations, I may refer to the directions for finding a square root. It is not my intention to explain this process here, but simply refer to the artifice. "The simplest way to extract square root on the comptometer is to act on the principle that in the series of odd numbers, 1, 3, 5, 7, 9, &c., the square of the number of terms always equals the sum of all the terms." On this a process of addition is devised, using the red numbers on the keys, which I find, even without much practice, is surprisingly rapid for the first three figures, but which, like the ordinary head and pencil way, becomes increasingly cumbersome with a greater number.

The comptometer is like all arithmometers in that, having found one product of two or more numbers, or having any previous result on the register, any further products of two numbers may be added to or subtracted from this, one at a time, without the necessity of writing down any intermediate result or of separately finding these products; and then, when this is done, the sums or differences of all the products may be divided by a final number. If a further division is required the comptometer differs from all arithmometers except Edmondson's in that the result is found on the same register as the previous dividend, and so it might appear that any number of divisions could be effected. This is not the case, as the quotient occasionally moves up the machine towards the left and so gets out of range, whereas in Edmondson's, as the machine is arranged in a circle, the quotients and dividends may chase each other round the machine without ever coming to a dead stop. In ordinary arithmometers the quotient gets on to the counter wheels, when nothing more can be done to it unless it is again transferred to the register.

The operation, therefore, that these machines can perform with the greatest advantage is of the form

$$\frac{ab \pm cd \pm ef \pm \ldots}{r},$$

whereas the operation that is most favourable for the use of logarithms is of the form

$$\frac{a^n\, b^m\, tab^p\, \theta \ldots}{r^q\, s^t\, tab^v\, \phi \ldots},$$

tab representing any of the tabulated logarithmic functions. This advantage is so great that formulæ are artificially manipulated until they are finally rammed into this form and are then said to be adapted to logarithmic computation. Now the advantages of the calculating machines referred to are so great, and they are in so many ways preferable to logarithms where they can be used, that it is just as important to adapt formulæ to mechanical computation by putting them where convenient into the first of these two forms. Then, according as they can be put into one or other of these forms, machines or logarithms should be used for the purpose of computation, and no attempt should be made to use either for work specially adapted in this way for the other.

It may perhaps be worth while, by way of example, to mention that in the large number of corrections of the scale readings to bring them to circular measure that I had to make in my experiments on the constant of gravitation, I found I could calculate $\theta - \frac{1}{3}\theta^3 + \frac{1}{5}\theta^5$ in less time on an arithmometer than was required to look up the angle in the trigonometrical tables.

A few final observations are desirable bearing on the comparison of the comptometer with arithmometers.

In the first place the comptometer makes a most aggravating noise, like a typewriter through a megaphone; but other arithmometers are noisy, none, however, so bad as this machine. The only silent arithmometer is that beautiful machine invented by Prof. Selling, but this is practically unknown in this country.

To my mind the comptometer, with its single figure operations, is not so convenient as the arithmometer for reducing and computing observations in the laboratory. Its success is only rendered possible by the fact that it is a key machine, for key strokes may be so very rapid. The operating numbers on most arithmometers are set by slides and that is relatively slow, the operation, however, by the handle afterwards is vastly more rapid. Selling's arithmometer is, however, a key machine for the setting, while the turning handle is replaced by a sliding movement, one complete slide doing the work of five turns of the handle. Again, the fact that there is no record of the operating figures actually given to the comptometer seems to be, for scientific work, decidedly a drawback.

On the other hand the construction is admirable, perfectly adapted to its purpose, and, I should judge, fairly indestructible. I would on this point only make one complaint, which, however, refers to a defect in no respect essential to the machine. I refer to the difficulty of reading the numbers on the register. The figures are elegant, with a great contrast between the thick and the thin parts, and they are upon a polished reflecting wheel face. They are seen through small windows in a polished metal plate. The result is they are not as legible as they ought to be; great care has to be taken to get a suitable light, and it is useless to sit facing a window. The 3's may be confused with the 8's, the 1's with the 4's, and the 0's with the 9's. If block figures were used, and if, further, they were dead white upon a black ground, or even the reverse, and were not seen through a shining plate, this little defect, which I am surprised to see in the product of an American shop, would be remedied.

I have made no comparison between the comptometer and the slide rule because a good slide rule, such as Gravét's, cannot be approached in convenience by any mechanism where the limited accuracy of the slide rule is sufficient, nor can wheelwork machines directly find the fourth term in a proportion in which the three other terms are numbers, their squares, or roots, or trigonometrical functions, or the reciprocals of these, nor can they give logarithms at sight.

The attempts that have been made to increase the accuracy of the slide rule by increasing its length are not, in my opinion, of much success, because to gain only one more figure ten times the length, at least, is necessary. The rule must then be broken up gridiron fashion, as in General Hannyngton's,[1] Prof. Everett's and Thatcher's, or wound in a spiral as in Fuller's, or be altogether peculiar as Tower's. When an extra figure has been gained in this way the extreme handiness of the slide rule is gone, as it can no longer be carried in the pocket, it takes longer to find the place, and, as a rule, the range is limited to mere simple proportion. Where the accuracy of 1/10 per cent. given by a 26 cm. rule, or 1/20 per cent. by a half-metre Gravét rule is not sufficient, I should prefer in general five-figure logarithms or a wheel-machine to an extended slide rule. Whether the wheel-machine should be a comptometer or an arithmometer must depend upon the character of the calculations most often met with. I have attempted in my preceding remarks to give the information necessary to enable any one to judge in his own particular case.

C. V. BOYS.

RECENT REPORTS OF THE SMITHSONIAN INSTITUTION.[1]

THE field of operations of the Smithsonian Institution is so extensive that it is impossible to survey adequately the work carried on in it. The liberality of the Institution has made many students of science acquainted with the researches and results of others, and has placed the whole world of scientific activity under an obligation. In addition, each of the departments under the direction of the Institution is a living centre of investigation, from which contributions to natural knowledge are continually emanating. These departments are the United States National Museum, the Bureau of American Ethnology, the International Exchanges, the National Zoological Park and the Astrophysical Observatory.

Following the precedent of several years, Prof. Langley gives, in the body of his report referred to in the footnote, a general account of the affairs of the Institution and its bureaus, while the appendix presents more detailed statements by the persons in direct charge of the different branches of the work. Independently of this the operations of the National Museum are fully treated in a separate volume of the Smithsonian Report, and the Report of the Bureau of American Ethnology constitutes a volume prepared under the supervision of the Director of that Bureau.

Parts of Prof. Langley's report are given below, together with references to some of the contents of the Smithsonian Report for 1899, and the Annual Report of the National Museum, recently received. Two recent reports of the Bureau of Ethnology will be noticed separately.

Astrophysical Researches.—Experiments in the solution of the problem of mechanical flight have been continued, and the Astrophysical Observatory has been active in the investigation of the solar spectrum. The first volume of Annals of the Observatory has been issued. It is devoted primarily, though not exclusively, to the investigation of the infra-red solar spectrum, its absorption lines and its variations in terrestrial absorption. This research, and the development of the sensitive bolographic apparatus with which it has been carried on, have largely occupied the Astrophysical Observatory since its foundation, and are a continuation of researches in which Prof. Langley was engaged for many years at the Allegheny Observatory.

As readers of NATURE are aware, successful observations were made of the solar eclipse of May 28, 1900. A considerable number of photographs of the corona were secured, some of which are upon an unprecedentedly large scale, and these, it is believed, will be of value in investigations of the nature of this still enigmatical solar appendage. A photographic search for hitherto unrecognised objects near the sun developed the fact that even in an ordinary sky, in an eclipse in which the reflected sunlight was brighter than usual, stars as small as the 8·3 magnitude could be secured.

The apparatus employed was designed, not so much for this, however, as for the obtaining evidence of possible intramercurial planets, but upon this latter point no final opinion can be given. Certain suspicious objects are found on the plates, but unfortunately observations of the same kind at other stations were unsuccessful, so that there is nothing with which to compare them. Studies are still going on, however, and it is possible that this part of the observations may yet yield results of interest.

The delicate and difficult observations upon the heat of the inner corona were made by means of the bolometer, and appear to have been quite successful, being perhaps the first trustworthy observations of the kind; they lend some additional weight to the view that the corona is something analogous to an electric phenomenon.

The Hodgkins Fund.—The different branches of research now progressing under grants from the Hodgkins fund are making satisfactory advances.

Prof. William Hallock, of Columbia University, New York, has supplemented his report of last year by a summary of the further progress of his investigation of the motion of an air particle under the influence of articulate speech. The instruments which Prof. Hallock has invented, and is now perfecting, have proved a great aid in this research, and will, he states, enable him to settle definitely the question of phase differences in the components of a complex sound.

Prof. A. G. Webster, of Clark University, reports the completion and successful application to the use for which it was designed of the new apparatus, perfected with aid from a Hodgkins grant, by means of which it is now possible to measure the intensity of rapidly varying sounds with an accuracy not hitherto attained. A grant has been made to Prof. Louis Bevier, of Rutgers College, for an investigation of vowel-timbre on the basis of the phonographic record.

The meteorological investigations with kites have been successfully continued at Blue Hill under the direction of Mr. Rotch with the assistance of a grant from the Hodgkins fund. In addition to these investigations, a Hodgkins grant has been made to enable Mr. Rotch to carry on a series of experiments in space telegraphy, it being thought that the unprecedented heights attained by kites might materially extend the range of communication by this method. In the preliminary experiments, however, kites were not used, sufficient elevation being attainable without them, but when the difference between the stations was increased from one mile to three, kites were employed to raise the transmitting and receiving wires. In the later experiments it was found, not unexpectedly, that the long wires, carried up and supported by kites, collected so much electricity as to interfere with and greatly complicate the messages sent from station to station. These interruptions seem to show that the limit of elevation for the receiving wire was under these conditions less than 500 feet. The greatest distance covered in the experiments was approximately twelve miles, from a wire supported by a kite about 200 feet above Blue Hill to the tower of Memorial Hall in Cambridge, which was used as the receiving station. These experiments draw attention to the fact that electrification increases with the altitude to which the wire is carried, and that it is always present, although varying with the meteorological condition of the atmosphere.

Dr. Carl Barus has been given a grant from the Hodgkins fund in aid of his experiments on atmospheric condensation. This research is supplemental to the experiments already conducted by Dr. Barus, as described in *Bulletin* No. 12, of the Department of Agriculture, and will be (1) a study of the origin, activity and growth of the condensation producing dust particles; their reactions on each other, their relation to electric radiation, &c.; (2) a study of the growth, &c., of water corpuscles after condensation; the reaction of corpuscles of different sizes on each other, &c.

A grant has been approved on behalf of Prof. Dr. R. von Lendenfeld, of the University of Prague, for a study of the motion of birds in actual free flight, a subject to which, although primarily known as a zoologist and meteorologist, Dr. von Lendenfeld's attention has been directed for years, and for the better understanding of which he has made numerous anatomical preparations, physiological observations, &c. The investigations of Dr. von Lendenfeld have been aided by the Society for the Advancement of Scientific Research in Bohemia, and also by the Austrian Government.

A grant from the Hodgkins fund has been made to Dr. V. Schumann, of Leipzig, for the prosecution of researches in connection with the spectral relations of atmospheric air. The apparatus by means of which Dr. Schumann has heretofore secured such noteworthy results being chiefly of his own invention, he has been permitted to apply the present grant to the further perfection of his instruments before entering upon his special experiments, which will be definitely reported upon as they progress.

Standards of Colour.—Mr. Robert Ridgway, curator of ornithology in the National Museum, published a number of years ago, for the use of naturalists, a handbook on colour, and he requested a grant from the Institution for a new edition. It appeared to Prof. Langley that a work upon a more extended scale and a somewhat different plan would be of value primarily to naturalists, but also in every department of science, to artists, and in many branches of industry.

At the present time there is practically no uniformity in the common use of colour names, one name designating, as a rule, as many as half a dozen different shades; nor is there any absolute method commonly available by which a person in one place can

[1] Report of Prof. S. P. Langley, secretary of the Smithsonian Institution, for the year ending June 30, 1900. Pp. iv + 117.
Annual Report of the Board of Regents of the Smithsonian Institution for the year ending June 30, 1899. Pp. lxiii + 672.
Report of the U.S. National Museum for the year ending June 30, 1899. Pp. xv + 598. (Washington: Government Printing Office, 1901.)

describe to a person in another the exact shade or tint meant by a given name. The production of a work which would obviate these difficulties and make available what might be called the "constants of nature" in colour, is directly in line with previous publications of the Institution in endeavouring to establish standards whereby a definite nomenclature in scientific and popular writing might be introduced.

Prof. Langley, after consulting with others expert in the matter, decided that it would be desirable, not only to secure more permanent tints, but to connect every tint published in the book with some definite wave-length in the spectrum, whether the solar spectrum or a composite one. The investigations of Prof. Rood and others show that it is difficult to do this directly, but that it can be effected by the use of intermediate means of comparison.

Again, experiments must be made to determine how far this large object (of connecting every tint employed with some definite wave-length or combination of wave-lengths of light) is practicable. If it be fully so, the work may be said to be in one sense something absolutely permanent, relating as it will to standards which can never alter with time, so that, as has been said, those who expect that their writings will be more permanent than the planet itself should take this method of illustrating them. The work promised such magnitude that a committee was appointed, and is now considering the subject.

Collected Papers.—The General Appendix to the Annual Report of the Smithsonian Institution may be termed a "source-book" of scientific history. In consists of reprints and translations of authoritative but popular scientific articles which appeared during the year of the Report. Some are addresses delivered in institutions concerned with the diffusion of knowledge, and others are papers contributed to scientific and other periodicals, and collectively they form an epitome of advance and opinion in all departments of science. There are in the volume before us (1899) no less than thirty papers of this kind, among them being translations of the following: influence of the wave-theory of light on modern physics, by Prof. Cornu; on the sense of smell in birds, by M. X. Raspail; have fishes memory? by Herr L. Edinger; the garden and its development, by Dr. P. Falkenberg; sea-charts formerly used in the Marshall Islands, with notices on the navigation of these islanders in general, by Captain Winkler; the peopling of the Philippines, by Dr. R. Virchow; list of the native tribes of the Philippines and of the languages spoken by them, by Prof. F. Blumentritt; and the sculptures of Santa Lucia Cozumahualpa, Guatemala, in the Hamburg Ethnological Museum, by Herr Herman Strebel.

National Museum.—Details in regard to the work of the U. S. National Museum are given in an appendix to Prof. Langley's report. To the geological collections were added some interesting fossil animals secured from the fields of Wyoming, and a large amount of zoological material was collected in Cuba and Porto Rico. There has also been transferred to the Museum the extensive and very valuable series of vertebrate fossils collected by the late Prof. Marsh during his connection with the United States Geological Survey. This collection aggregated five car-loads, and is particularly rich in specimens of the gigantic Dinosaurs, besides fifty skulls of Titanotherium, probably the best specimens in existence.

The Annual Report of the Museum for 1899 is largely devoted to a description of the collection of non-metallic minerals in the department of applied geology, by Mr. G. P. Merrill. The term non-metallic is used to designate minerals which, as exhibited in the Museum, are utilised in other than metallic forms. The subjects of remaining papers in the Report are:—A Primitive frame for weaving narrow fabrics, and pointed bark canoes of the Kutenai and Amur, by Dr. O. T. Mason; an early West Virginia pottery, by Mr. W. Hough; and a descriptive catalogue of a collection of objects of Jewish ceremonial in U. S. National Museum, by Drs. C. Adler and I. M. Casanowicz.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. G. S. TURPIN, headmaster of the Swansea Intermediate and Technical School, has been appointed to succeed Dr. Gow as headmaster of the Nottingham High School. Particulars as to the vacancy thus caused at Swansea will be found in our advertisement columns.

THE council of University College, London, have appointed Mr. J. D. Cormack, of the University of Glasgow, to the chair of mechanical engineering in this College, vacant by the resignation of Prof. Hudson Beare on his appointment as regius professor at Edinburgh.

The Education Bill (No. 2), was read a second time in the House of Commons on Tuesday, after a long and animated debate. As a consequence of the Cockerton judgment, the question had to be determined whether School Boards were the proper authorities to deal with secondary education or not; and the Government decided against them. The Bill is the first step towards the establishment of single local authorities connected with County Councils for the control of the whole of the work of secondary education in their districts.

THE Liverpool City Council unanimously adopted the following resolution at a meeting held on July 3:—"That the Council has observed with much satisfaction the growth and progress of the University College, and in view of the fact that the college authorities are taking steps to procure the establishment of a separate University for Liverpool records its opinion that it is desirable in the interests of higher education in the city that such a University should be established." It is understood that, though there has not yet been any appeal to the public, about 100,000*l.* has already been promised for Liverpool University, which will bring up the capital value of University College to about 600,000*l.*, and the promoters are sanguine that there will be little difficulty in raising this to 750,000*l.* The council of University College have elected Dr. E. W. Marchant to the lectureship in electrotechnics vacated by Mr. Alfred Hay's appointment to a professorship at Coopers Hill.

THE University of Birmingham is fortunate in having a strong man like Mr. Chamberlain to plead its cause and advance its interests. At the first congregation of the University, held on Saturday last, he again directed attention to the national importance of higher education and research, and referred to the liberal provision made for work of this kind in other countries. "I am convinced," he said, "that unless we overcome the innate conservatism of our people in regard to the application of the highest science to the commonest industries and manufactures in our land, we shall certainly fall very far behind in the race." Though the fact involved in this statement has been persistently brought forward in NATURE for many years, it cannot be too frequently reiterated in public to rouse wealthy citizens to a sense of their responsibilities as regards provision for national progress, and create a higher regard for scientific work than is at present possessed by Englishmen in general. It is not necessary to enlarge here upon the facilities for scientific work abroad, for scarcely a week passes without our having to record munificent donations by States and individuals for the erection of buildings in which such work can be carried on under favourable conditions. Mr. Chamberlain mentioned in his address that the Charlottenburg Technical High School cost half a million of money, and this is but one instance of many. A modern University ought at least to secure an equal sum of money to build and equip its scientific side, especially when the ideals are those sketched by Mr. Chamberlain in the following words:—"I venture to lay down four qualifications as necessary to a perfect University. In the first place, it should be an institution where all existing knowledge is taught. Such a University may, perhaps, never yet have been attained; want of means may always prevent it, but at least that was the object at which we should aim, and we should never rest satisfied until we can say that no student desirous of instruction in any branch of learning shall be turned hungry away from the doors of this University. No doubt the enormous development of knowledge, and especially of its scientific side, during the present century requires a certain specialisation in the teaching of that knowledge, and I think it may be desirable, I think it may be necessary, that Universities also should be specialised, and that one University should pay more attention than another to particular studies; but I believe at the same time that it would be fatal if in our desire as a modern University to give a special development to the practical and thorough teaching of our scientific work, it would be a great mistake, I say, if we were to exclude or to neglect the older branches of learning. Well, then, in the second place a University is a place where the knowledge that has been acquired has to be tested. And as to that I will only say that in the multiplication of examining bodies I hope that nothing will be done, either by us or by our successors, to lower the standards of proficiency, whether in the ordinary pass or in the highest honours. Then the third feature to which I should call attention, and which I am inclined to say is the most important of all, is that a University should be a place where knowledge is increased and where the limits of learning are extended. Original research, the addition of something to the total sum of human knowledge, must always be an essential part of our proposals. We want to secure that those who teach in this University shall never cease to learn, and that those who are students shall unite with them in the work of fresh and new investigation. And, lastly, a University is a place where the application of knowledge must be indicated and directed. That perhaps brings us nearer to what may yet be the distinctive feature of our University. At all events we start with the belief that here we are going to combine theory with practice, and to see that in our University we shall combine both in one course of instruction, with due regard to the needs of our own time and of our own district. And now, if I may summarise in one sentence what I have been saying, it is that a University should be a place where knowledge is taught, tested, increased and applied."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Meteorological Society, June 19.—Mr. W. H. Dines, president, in the chair.—A paper by Mr. H. Helm Clayton, of the Blue Hill Observatory, U.S.A., on the eclipse cyclone, the diurnal cyclones and the cyclones and anti-cyclones of temperate latitudes, was read by the secretary. The author has discussed the meteorological observations made along the path of the total solar eclipse in the United States on May 28, 1900, and also those made during three previous eclipses. He finds that a cyclone follows in the wake of the eclipse—though the changes are very minute and feeble—the fall of temperature developing a cold-air cyclone in an astonishingly short time, with all the peculiar circulation of winds and distribution of pressure which constitute such a cyclone.—A paper, by Mr. F. Napier Denison, of Victoria, British Columbia, on the seismograph as a sensitive barometer, was also read by the secretary. A Milne seismograph was installed in 1898 at the Meteorological Office, Victoria, B.C., and the author has since that time compared its movements with the changes of atmospheric pressure recorded by his "aërograph." He finds that when the barometric pressure is high over the Pacific slope from British Columbia southward to California, while off the Pacific coast the barometer is comparatively low, the horizontal pendulum of the seismograph tends to move towards the eastward. This movement appears to be due to a distortion of the earth's surface, caused by the heavier air over the Pacific slope depressing the underlying land surface below its normal position, while, on the other hand, the comparatively light air over the adjacent ocean tends to allow the sea and earth beneath to rise above its normal level. It has been found that when an extensive storm area is approaching from the westward, and often eighteen to twenty-four hours before the local barometer begins to fall, the pendulum of the seismograph swings steadily to the eastward, completely masking any diurnal fluctuations that might have existed, as the storm area approaches, and in the event of it being followed by an important high area, the pendulum will begin to swing towards the westward before it is possible to ascertain this area's position on the current weather charts.

Anthropological Institute, June 19.—Extraordinary joint meeting with the Folklore Society. Prof. A. C. Haddon, F.R.S., in the chair.—Prof. Haddon vacated the chair in favour of Mr. E. W. Brabrook, president of the Folklore Society.—Mr. E. S. Hartland exhibited the collection of Musquakie beadwork and other objects presented by the late Miss Florence Grove to the Folklore Society, and to be deposited in the Museum of Ethnology at Cambridge.—Mr. R. Shelford exhibited two charms against stomach-ache from Borneo.—Mr. H. Balfour read a paper, by Mr. W. G. Aston, C.M.G., on Japanese Gohei and Ainu Tirao.—Mr. N. W. Thomas read a paper, by Mr. E. Tregear, on the spirit of vegetation.

DUBLIN.

Royal Dublin Society, May 22.—Sir Howard Grubb, F.R.S., in the chair.—Prof. Hartley, F.R.S., and Mr. Hugh Ramage communicated a paper upon the banded flame-spectra of metals. This was a continuation of some former work on flame spectra at high temperatures by Prof. Hartley, published in the *Phil. Trans.*, in which it was shown that fluted and banded spectra are characteristic of many metals. The list is now extended, banded and fluted spectra of copper, gold, palladium, zinc, cadmium, aluminium, beryllium, lanthanium, indium and thallium have been photographed and the principal bands in their spectra measured. A banded spectrum has also been obtained from iridium. In well-defined groups, such as magnesium, zinc, cadmium, aluminium, indium and thallium, the spectra appear to be homologous.—Prof. Hartley communicated a paper on a theory of the molecular constitution of supersaturated solutions. The chemical constitution of these solutions, which exhibit the well-known phenomenon of sudden crystallisation when either a crystal of the same salt or one of the same constitution and isomorphous with it gains access to the liquid, has been thus explained by the author. When a supersaturated solution is formed the salt in solution is a definite hydrate, but it is not the same hydrated salt as that which crystallises out. The cause of the supersaturation is the greater solubility of the one hydrate over the other at a given temperature; and its conversion into the other by combination with some of the water, acting as a solvent, causes its sudden solidification. In cases where the supersaturated solution is prepared by digesting a dehydrated salt in cold water, the course of change is first hydration, secondly solution, and thirdly crystallisation. Reference is made to the work of H. Le Chatelier, Wyrouboff, and others.—Sir Howard Grubb communicated a note on a case of true stereoscopic effect obtained from a single picture, which he demonstrated by means of a model.—Mr. F. W. Moore exhibited and described a living specimen from the Botanic Garden, Glasnevin, Dublin, showing the germination of the double cocoa-nut (*Lodoicea sechellarum*).

EDINBURGH.

Royal Society, June 17.—Prof. Sir William Turner, K.C.B., in the chair.—Prof. Cossar Ewart, in a paper on in-breeding, gave the results of a number of experiments he had tried on pigeons, rabbits, mares and goats, and examined in the light of these the views as to the injurious effects of in-breeding which were held by certain naturalists. Thus Darwin had concluded that in-breeding was injurious; other biologists, including Weissmann, that it was not. Similarly, Huth and Westermark differed as to the harmfulness of consanguineous marriages. The general result of his own experiments led Prof. Ewart to the conclusion that in-breeding led to loss of constitutional vigour and sometimes of size, but not to loss of fertility; and the diversity of view held by naturalists he regarded as being due to the fact that members of one family often differed in constitution to a marked degree, brothers and sisters, for example, differing more than their parents, and there being occasionally greater similarity between second cousins than between first cousins. It was also pointed out that, in certain circumstances, in-breeding by arresting reversion (which was favoured by crossing) tended to favour the appearance of new varieties.—Mr. F. H. A. Marshall read a paper on hair in the Equidæ. It was found that the hairs of the three principal types of zebra were fairly distinct, while the Somali zebra stood quite by itself, a conclusion agreeing with that of Nathusias. The hairs of horses showed considerable variability dependent largely on the breed, while those of zebra-horse hybrids, so far as the observations went, were fairly constant in character. The hairs of the mane, as well as those from the sides of the body, were also dealt with. The paper concluded with a reference to a suggestion by Nathusias that, if the telegony hypothesis were true, we might expect to find evidence of it in the hair characters of the "subsequent foals." Such evidence was, however, utterly lacking.

PARIS.

Academy of Sciences, July 1.—M. Fouqué in the chair.—Chemical equilibria; phosphoric acid and the chlorides of the alkaline earths, by M. Berthelot. The author's recent experiments on the subject are continued, the reactions dealt with in this paper being those occurring between phosphoric acid, monosodium phosphate or disodium phosphate, and calcium, barium or magnesium chloride. It is found that the number of equivalents of the alkaline earth entering into combination with a molecule of precipitated phosphoric acid varies from 2 to 4, according to the nature of the substances and the time which has elapsed since the commencement of the reaction.—New treatment of niobite; preparation and properties of fused niobium, by M. Henri Moissan. The native mineral, consisting chiefly of niobic and tantalic acids together with iron, manganese and silica, is heated with charcoal in the electric furnace, a fused mass of niobium and tantalum combined with carbon being thus obtained. The two metals are separated by Marignac's method, based on the different solubilities of sodium fluoniobate and fluotantalate, the former salt being finally calcined and fused with charcoal. Niobium is thus obtained as a very hard, metallic mass, having a melting point above 1800°; it is almost unacted on by acids, and does not decompose water vapour at a red heat. When heated in oxygen, it burns with the production of niobic acid.—New nebulæ discovered at the Paris Observatory, by M. G. Bigourdan.—Observations at sea of the comet of May 1901, by MM. Doué and Rivet. The observations were made in the course of a voyage from Tahiti to Panama.—On a mechanical interpretation of the principles of thermodynamics, by M. André Séligmann-Lui.—On the indices of refraction of mixtures of liquids, by MM. J. de Kowalski and Jean de Modzelewski.—The dielectric constant of a mixture of liquids has been shown not to be connected by any simple law with that of its constituents, and it seemed of interest to determine whether this anomaly held with regard to the index of refraction, which is closely connected with the dielectric constant. Experiments with mixtures of alcohol and benzene, alcohol and toluol, and ether and chloroform have shown, however, that such is not the case, the index of refraction of each of the pairs of mixed liquids being readily calculated from the indices of its constituents.—Hertzian waves in storms, by M. F. Larroque. A demonstration of the production of Hertzian waves in storms and their transmission to great distances.—Acidimetry of arsenic acid, by MM. A. Astruc and J. Tarbouriech. If methyl orange is employed as indicator, one molecule of arsenic acid is neutralised by one molecule of potash, soda or ammonia and by half a molecule of baryta, strontia or lime, identical results being obtained in the cold and on heating. With phenolphthalein, however, two molecules of an alkali or one molecule of an alkaline earth are required; on boiling, no difference is observed in the case of the former, but one and a half molecules of baryta, strontia or lime are then required for neutralisation.—On the uncoloured compound of sodium tetrazotolylsulphite with ethyl-β-naphthylamine and its conversion into a colouring matter, by MM. A. Seyewetz and Blanc. The coloured substance, a red insoluble powder, is formed by the exposure to light of the uncoloured compound, and is identical with the product of the action of ethylnaphthylamine hydrochloride on tetrazotolidine chloride.—On the action of benzaldehyde on sodium menthol and new methods for the preparation of benzylidenementhone, by M. C. Martine. Sodium menthol resembles sodium borneol in its action on benzaldehyde, the product of the reaction being benzylidenementhone; this compound is also formed by the action of benzaldehyde on the sodium derivative of menthone.—Combinations of camphor with β-hydroxy-α-naphthaldehyde, by M. André Helbronner. The new compound, $C_{23}H_{26}O_2$, which is designated ethoxynaphthalcamphor, crystallises in brilliant white crystals melting at 100°; it is dextrorotatory. On reduction with sodium amalgam it yields a compound melting at 112°, which bears the same relation to the parent compound as benzylcamphor to benzalcamphor. Metoxynaphthalcamphor, which has also been prepared, melts at 78° and its reduction product at 96°.—Action of bromacetophenone on sodium acetylacetone, by M. F. March. The reaction studied gives rise to a triketone of the constitution $(CH_3 - CO)_2 = CH - CH_2 - CO - C_6H_5$, which forms large, colourless crystals melting at 57–58°; on treatment with soda it yields acetophenonacetone.—Action of hydrogen sulphide on acetylacetone, by M. F. Leteur. When hydrogen sulphide is passed into a solution of acetylacetone in concentrated hydrochloric acid, an abundant deposit of needle-shaped crystals is produced. This compound melts at about 163°, and is shown by analysis and by cryoscopic molecular weight determinations to have the formula $(C_5H_8S_2)_2$.—Influence of sodium fluoride in the saccharification, by seminase, of the carbohydrates contained in the seeds of leguminous plants, by M. H. Hérissey. Sodium fluoride, which was used as an antiseptic in the study of the saccharification, was found to exert a marked favourable influence on the process.—On epithelial centrosomes, by M. P. Vignon.—Observations on the root of vascular cryptogams, by M. G. Chauveaud.—On the vegetation of punctiform nostoc in the presence of different carbohydrates, by M. R. Bouilhac. Sucrose, maltose or starch may replace dextrose in the cultivation of nostoc, whilst with lactose or lævulose only a very feeble vegetation is obtained.—Generality of the fixation of metals by the cell-wall, by M. H. Devaux. The fixation of metals by the cell-wall in plants, previously demonstrated in the case of injurious metals such as copper, silver and lead, is now shown to be a very general phenomenon. The proportion of metal absorbed is always small, and is not sensibly increased by the use of more concentrated solutions.—On the optical data relative to the macle of pericline, by MM. F. Pearce and L. Duparc.—On the presence of Devonian strata containing *Calceola sandalina* in the Western Sahara, by M. G. B. M. Flamand.—Action of currents of high frequency on the urinary secretion. Information furnished by chemical analysis, by MM. Denoyés, Martre and Rouvière. During electrical treatment there is an increase in the amount of urine, and in the urea, uric acid, total nitrogen and salts contained therein.—Passage of carbon monoxide from the mother to the fœtus, by M. Maurice Nicloux.—Cellular heredity, by MM. A. Charrin and Gabriel Delamere.—On a reaction characteristic of pure waters, by M. H. Causse. Pure, uncontaminated water restores the colour of crystal violet which has been previously decolourised by sulphurous acid, but has no action on decolourised magenta or on paradiazobenzene sulphonate. In the presence, however, of human or animal excreta the colour of the two last mentioned reagents is restored, whilst the decolourised crystal violet is unacted on.

NEW SOUTH WALES.

Linnean Society, May 29.—Mr. J. H. Maiden, president, in the chair.—Notes on the botany of the interior of the Colony, part iii., by Mr. R. H. Cambage. Part iii. is descriptive of the botany of the country extending from the Bogan to the Lachlan, *viâ* Nymagee.—Revision of the Genus Paropsis, part vi., by Rev. T. Blackburn.—The nature of the bacteroids of the leguminous nodule and the culture of *Rhizobium leguminosarum*, by R. Greig Smith. The bacteroids of the leguminous nodule are neither higher nor lower types of growth, but are normal bacteria contained in a bulky branching capsule. A medium prepared from leguminous plants is not essential for the growth of *Rhizobium* as claimed by Hiltner. The author has grown the organism for more than a year on media devoid of all plant infusion.—On one of the so-called honeysuckles of Lord Howe Island, by J. H. Maiden. In the Society's *Proceedings* for 1898 (p. 126), the author described a tree under the name *Cupania Howeana*. He believes that this is identical with the plant described by Radlkofer in 1886 as *Guioa coriacea*, and gives the complicated synonymy of the species. The author tabulates the radical alterations that Radlkofer proposes in the nomenclature of Australasian Sapindaceæ and submits them for further consideration of Australian botanists since they were not adopted by Mueller.

MODERN ELECTRODYNAMICS.

Électricité et Optique: la Lumière et ses Théories Électrodynamiques; leçons professées à la Sorbonne en 1888, 1890 *et* 1899. Par H. Poincaré. Deuxième édition, revue et complétée par J. Blondin et E. Néculcéa. Pp. x+642. (Paris: G. Carré et C. Naud, 1901.) Price Fr. 22.

IN the present state of electrical and general physical theory there are probably few undertakings more useful towards progress than a critical discussion of the views of other writers by one who has himself thought deeply and read widely on the subject.

We may recall the stimulus afforded to the progress of Maxwell's electric theory on the Continent by Helmholtz's early series of critical memoirs (now largely out of date, having served their purpose) that were devoted to the examination of the relation in which that theory stood to the views of electrical action then current.

The lectures of M. Poincaré, reported and published by his pupils about ten years ago, possessed great interest as being an account of the then fresh advances constituted by the experimental investigations of Hertz, from the hand of a writer who occupied one of the highest positions both in the domain of pure mathematics and in that of its physical applications. The writer's unlimited command of analysis and the range of his interests were certain to shed new lights on the subject-matter of which he undertook the exposition. A second edition of the "Électricité et Optique" is now published in a volume of 640 pages, of which about half consists of a report of lectures delivered at the Sorbonne in 1899 on the still more recent improvements of Maxwell's electrodynamic theory which are associated largely with the name of H. A. Lorentz. It is this latter half of the book, giving the writer's reflections and criticisms on a development which is still fresh, that will naturally present the chief interest for others who have meantime been following the progress of the subject.

The main feature of the new standpoint is the resuscitation of the idea of electricity as representing something permanent like matter. In Maxwell's later writings, in which he was mainly occupied in eliminating the hypothetical illustrations and models which had guided him to his theory, but were not logically necessary to its formal exposition, there was a tendency for the older idea of an electric charge, as representing something real, to be eliminated. According to his view, the electric current always flows in closed circuits like a current of an incompressible fluid, so that there is nowhere any tendency to accumulation of electrodynamically effective electricity. It seemed, therefore, possible to do without any introduction in detail of an entity whose flow was restricted by the condition that the quantity of it in any given volume could never alter. This conception of circuital electric flow (to use Lord Kelvin's term) required the ascription of properties the same as those of currents to electric excitation both in dielectric material substances and in the free æther itself. The displacement current thus introduced is, in fact, the fundamental feature of Maxwell's electrodynamics. Its assumption led directly to a simple and perfectly complete theoretical account of the electrodynamics of material systems at rest, on the basis of laws established long before by Ampère and Faraday; the application to bodies in motion was, however, left by Maxwell in an incomplete and tentative state. In 1872, when he published his treatise, the circumstance that the laws of electrolysis imposed the idea that electricity was in some sense or other atomic was definitely realised, but with a certain reluctance; while in the treatment of bodies in motion the explicit recognition that a moving charge acts as a current had, owing to an oversight arising from his preoccupation with the medium, to be formally introduced into his equations by Fitzgerald ten years later, though Maxwell fully accepted such action as a fact all the time.

This plan of ignoring electricity and treating electrodynamics on the basis of a uniform medium with physical constants affected by the presence of matter, and subjected to various vector disturbances whose nature is unknown, but which are connected by partial differential relations expressing the laws of Ampère and Faraday, has been very fully developed by Heaviside and by Hertz. In both cases compensation is sought for the variation of the energy of each element of the medium, solely in the work of tractions exerted on its surface by the surrounding parts. In Heaviside's discussion the problem was treated with great generality and comprehensiveness; it will suffice here to pass in review the salient features of the more concise analysis advanced by Hertz. The treatment of stress by the method of energy requires displacement of the medium; and so the problem of ponderomotive forces becomes related to the general question of moving media, which is the part of the subject that provides the crucial tests of theory. The electromotive phenomena in media at rest are, on the other hand, all involved in the adoption of the aforesaid laws of Ampère and Faraday, as a description of the properties and behaviour of the medium. The same description is extended to media in motion after the manner of Faraday, and the deductive part of the argument is there confined to the determination of the ponderomotive mechanical forces. To obtain them, Hertz subjects his single uniform medium, which he takes to be the seat of the electric and magnetic energy, to static strain without finite motion, and computes the time-rate of alteration of the energies thereby produced in a given element of its mass. He supposes that the polarisations per unit volume, being affections of the medium, are simply convected along with it. If the element of mass were dynamically self-contained and not subject to tractions from the surrounding parts, its energy would be conserved so that this time-rate of alteration should vanish. As it is, the alteration does not vanish, but represents the work done in the element by the tractions acting on its surface. As the element is part of an elastic medium, the work of such surface-tractions ought to be expressible in the form of work of the stress-system, existing in the element, to which these tractions belong. Now the expression for the variation of the energy is thrown by Hertz into the latter form, in fact without the use of any electrodynamics in the analysis; and this leads him at once, for the case of isotropic media, to a self-conjugate electromagnetic stress-system, the same as Maxwell's, as providing the reacting mechanical forces required for equilibration of the outstanding energy. But for æolotropic media there arises a bodily torque in addition to this stress; this torque is included in Maxwell's general type of magnetic stress, and prevents it from being self-conjugate for that case. Hertz is unwilling to admit such a type of stress, which could not exist in an ordinary elastic solid; but he is at a loss to know what to do with this new part, and simply drops it, retaining the self-conjugate part as the stress in his electric medium. But for this the theory would be a consistent one on his premisses; and the result for the free æther, or wherever there is no material polarisation, is, in fact, the stress which Maxwell showed was competent to represent the actual mechanical forces. It is to be observed that this is all that is to be got out of the statical application of the principle of energy to his medium; the kinetics of the electromotive play being assumed as known, outstanding variations of the energy in slow changes are to be ascribed to the work of mechanical forces. No success has been achieved in the problem of reducing the electromotive play in media in motion to definite self-contained dynamics on any other basis than the theory of electrons; the charge must consist of discrete independent elements, each with its own electric field. The mode of treatment here sketched introduces, among other things, a mechanical force of an electric field on changing magnetic polarisation as the counterpart of the known mechanical force of a magnetic field on changing electric polarisation; this, on the theory of electrons, is non-existent.

The treatment of electrodynamics on the basis of discrete electrons is a branch of statistical molecular theory, like the kinetic theory of gases, and involves the refined considerations connected therewith, including the estimation of averages instead of the following out of individuals. The care that is thus necessary in the analysis may be illustrated by a temporary slip that has crept in at the beginning of the discussion of Lorentz's theory (§ 333), in which the single principle of continuity of flux of true electricity appears as a consequence of the addition of two independent formulæ, (3) and (4), neither of which appears again. They cannot be both true, or there would be two such principles of continuity instead of one. It would seem that the term density has been inadvertently used in two different senses, ultimately as the volume density of electric charge in the medium which depends on how closely the electrons are packed in it, but meanwhile as the density of electricity in an electron, supposed to be itself a small and rigid though mobile volume-distribution of charge. This local oversight, doubtless due to imperfect reporting of the lectures, illustrates an actual disadvantage of a completed hypothesis, which insists on a full specification of an electron, over the less complete physical specification, which, recognising that there is more in the constitution of the molecule of matter than our philosophy may ever reach, is content to regard it simply as the unknown central point or pole of its surrounding field of force.

The general plan of development of electrodynamics on this basis that is adopted by M. Poincaré consists in writing down equations of motion for each electron, by assigning to it a mass and considering it to be acted on by the averaged or smoothed-out electric and magnetic forces of the field that surrounds it, and finally passing to equations for the medium in bulk by summing or averaging the results for all the electrons per unit volume. This method is in keeping with the astronomical traditions of mathematical physics, in which the problem is put in definite terms at the beginning, and the analysis is confined to surmounting the difficulties, purely mathematical, that arise in its unravelment. There is, however, a different kind of theoretical physics which has had more success in this country, which recalls the names of Young, Stokes, Kelvin and Maxwell, and has more recently in Germany been illuminated by the example and inspiration of Helmholtz. Care is taken to avoid an irrevocable formulation of the problem in advance, only its broad dynamical features being worked in; while all the light that cognate but better understood branches of physics can shed by way of illustration or analogy is pressed into service. Thus, instead of writing out isolated equations of motion for the ideal case of a single electron—on the tacit assumption that no other electrons are near which would disturb the averaged field that is alone supposed to affect it—it is recognised that electrons, possibly in very large number, are somehow involved in the structure of each individual molecule, and that the fundamental and essential element in the physics of matter in bulk is this permanent molecule considered as a single free vibrating system, with free periods producing a radiant spectrum, which are involved in the intrinsic mutual influence of these oscillating electrons. The simplest type of framework for the structure of such a system is to assume provisionally a gyrostatic orbital constitution of some kind, which assists in holding its parts together in some such way as the whirling motion holds together a vortex ring in fluid. Our dynamical plan is thus now no longer fixed, but flexible; in fact it must remain so until we can form a definite representation of such a molecule instead of only a general idea of it. Yet the uniformity of physical law for matter in bulk shows that we ought to be able to develop our synthesis without waiting for such knowledge, which may even quite possibly be unattainable. In this procedure we must attend primarily to such activities of the molecules as can be cumulated by addition, so as to produce aggregate results expressible per unit volume of the medium, and eliminate the remaining non-cumulative disturbance which is related to practically irreversible or thermal phenomena. Of the former class is the strain in the configuration of the molecule produced by the electric or magnetic field in which it is situated, this distortion being represented for statical purposes by a single vector quantity, the induced electric or magnetic moment of the molecule, which aggregates into induced polarity of the material medium. Such, also, are the types and energies of free vibration about the steady configuration, which have been analysed in their aggregate into definite periods by the spectroscope. Here our knowledge is related to general principles rather than special systems, and progress is possible, thanks to the purely abstract general formulation of dynamics by Lagrange and Hamilton, and also to the supports and signposts afforded by such phenomena as anomalous optical dispersion and the magnetic subdivision of spectral lines. Outside such properties our power of tracing relations is very limited and imperfect, in the absence of control over the individual molecules, there being little to go upon except the two principles of thermodynamics, those of energy and entropy. The difference between the two points of view, the definite but partial and limited mathematical illustration and the wider but largely undetermined model, crops up, for example, in M. Poincaré's discussion of conducting media (§417), in which the combination of polarisation with conduction arising from wandering ions does not appear to suggest itself: "remarquons d'abord qu' ayant affaire à des conducteurs on n'a plus de polarisation," so that he has only to deal with electric current and electric density, doubtless in some degree with a view to save complication in a didactic exposition; whereas from the other more physical representation of a material medium one does not readily conceive a state of affairs in which only conduction and convection of free charges are present, but would proceed rather to examine under what circumstances polarisation can be practically neglected in comparison with conduction. This, of course, can be done in ordinary electrodynamics, as was doubtless in the writer's mind. But in the optical phenomena of metals it was recognised by Maxwell himself from the earliest stages—thanks mainly to the physical models on which he cultivated his ideas—that both agencies were essential; while recent closer examination has shown (cf. *Phil. Trans.*, 1895 A, p. 711, and in detail in recent papers by Drude) how naturally their combination represents the general features of metallic reflection as revealed by the most valuable and extensive measurements of Drude and other experimenters.

In working out the analysis, our author follows Lorentz in calculating directly the electrodynamic effects propagated from the moving electric charges which are the source of all the disturbance. He expresses this in terms of the "retarded vector potential" of the true current, a vector whose components are the potentials of the three components of its distribution, considered, however, as travelling out from them and becoming established around them with the velocity of radiation. A procedure which concentrates attention on the simply extended though molecularly constituted medium, to the exclusion, as far as possible, of the individual moving electrons, can get on more simply in Maxwell's manner by using the fictitious total current, which includes æthereal displacement as well as translation of charges; then the retardation of the vector potential is dispensed with, and all the functions are referred to the same instant of time, so that attention can be concentrated on the processes of averaging, undisturbed by mathematical complexities.

The distinction above sketched between the crystallised mathematical and the fluent physical point of view is at the root of what is a prominent characteristic of the writer's criticism. The development of electrodynamics appears as split up into so many independent and largely irreconcilable theories; there are headings, "theorie de Weber, de Maxwell, de Helmholtz, de Hertz, de Lorentz, de Larmor." Whereas on the view which works by models and general ideas rather than by formulas there is but one theory of electrodynamics—at any rate only one æther-theory—which has put on various modifications and has adopted various forms of expression, in the course of gradual improvement so as to become a closer and closer mental picture of the orderly course of phenomena; the subject presents itself rather as a continuous historical development, into which somewhat different paths all converge, than as a series of competing modes of explanation.

There is one feature in M. Poincaré's exposition for which the English reader will be grateful. A considerable trouble in the assimilation of mathematical investigations on this subject is the diversity of the notations (not to speak of systems of units) that are in use. All the available letters of most available alphabets have been pressed into service to represent the numerous types of quantities that occur; and if there is not a consistent basis of usage it must follow that the same symbol will be made to represent different things by different writers. M. Poincaré has kept as close as circumstances allowed to Maxwell's own notation, thereby acting up to the appeal of Boltzmann ("Vorlesungen über Maxwell's Theorie," 1891, preface), who found it necessary to actually construct a key for his own use to connect the notations of the principal German writers. Although the simplifications introduced by Heaviside, and subsequently in more formal guise by Hertz, did much to clear away the unessential accumulations that had overlaid Maxwell's theory, they did not in any sense transform it; and recent developments may be held to have justified the superiority, as a working basis for further advance, of the original elastic framework in which Maxwell set the theory, over the condensed *précis* of established results by which Hertz temporarily replaced it. It seems, therefore, unfortunate that the condensation of notation which was a part of Hertz's modification should have reacted to introduce some confusion in the notation of the more complete theory.

The development of electrodynamics, which was firmly established as the proximate foundation of all physical science, certainly of all that has relation to the æther, by Maxwell about forty years ago, has been going on with rapidly accelerated progress, both on the experimental and on the theoretical side, during the last ten years. New points of view have rapidly come up, have sometimes been as rapidly transcended. It is not surprising, therefore, that the discussion in the last chapter, which mainly relates to the mechanical and *quasi*-mechanical models of the British school, is somewhat out of date, indeed, it is largely constructed on the basis of an abstract, published in advance, of an imperfect first draft of theory contained in a memoir of date 1894, much as a palæontologist reconstructs a fossil organism from some of its bones. In the recent Lorentz-memorial volume M. Poincaré has himself revised some of his positions.

It is by this sort of discussion that crude theories are sifted and worn down into symmetry and order. And it is matter of congratulation that an analyst of M. Poincaré's vast command of all the resources of modern mathematics finds time not only to apply his genius to a thorough revision of the methods of mathematical astronomy, but also to survey the field of general physics as he has done in this interesting volume. In these days of extreme specialisation such surveys promise a special harvest, but few have sufficient breadth of learning to undertake them. The modern development of the theory of functions arose largely from transplanting the ideas of flux and force of physical mathematics into purely abstract problems. In astronomy, M. Poincaré's work has partly repaid the debt; it remains to be seen whether in electrodynamics a further instalment will be repaid, or analysis again become the debtor.

Anyhow, while pure analysis is ramifying into vast new regions and becoming more and more specialised, it is fortunately still possible for a single person to acquire an effective knowledge of the whole domain of theoretical physics. As in literature, so in scientific exposition, the saving virtue is style. If we call to mind the history of any of the theories which form the established heritage of common knowledge—such as hydrostatics or pneumatics—in their early inception they presented just as complex problems as the theory of the æther does now. But by the efforts of successive generations of expositors they have gradually been worn down, and the artificial appliances of symbolic reasoning have been eliminated or illuminated by the cultivation of new ideas and modes of expression. A theory of the æther hardly existed in any adequate sense half a century ago. Progress has recently been so rapid both on the purely scientific side, and in the reaction of modes of thought that have been fostered by industrial developments, that in a short time we may be able to picture to ourselves the operation of the æther with as much clearness and directness as we now understand the functions of the atmosphere. J. L.

GILBERT WHITE OF SELBORNE.

The Life and Letters of Gilbert White of Selborne. Written and Edited by his Great-Grandnephew, Rashleigh Holt-White. Two Vols. 8vo. Pp., Vol. I., xv + 330; Vol. II., ix + 300. (London: John Murray, 1901.) Price 32*s.*

The Natural History of Selborne. By Gilbert White. Pp. vii + 381. (London: J. M. Dent and Co.) Price 1*s.* 6*d.* net.

NOTHING nearly as good as Mr. Holt-White's book has ever yet appeared about Gilbert White; it supersedes Bell's two volumes, to which we have so far had to go for the real characteristics of the great naturalist, and it is hardly possible that it will ever itself be superseded. In its skilful treatment of materials it is amply worthy of its dedication to a great scholar, the present Provost of White's College. The editor has been content to let White and his correspondents speak for themselves, but rarely interposing to set us right on some misconception, or to explain (often, it is clear, after much expenditure of time and trouble) who are the persons referred to in the correspondence; and the result is one of the most delightful stories of a quiet life ever told in our language. As we reluctantly close the second volume, we feel that we now know White perfectly well as he really was. There is no need for a reviewer to anticipate the pleasure of readers by attempting to copy the picture.

It should be said, however, that this is not only a book for naturalists or lovers of nature, but for readers of every kind. Indeed, the charm of it seems to lie chiefly in the picture of life and manners it gives us—of the life of quiet country folks, with sedate but real interests of their own, using their time well, and sharpening their faculties continually under the gentle and unconscious stimulus of their alert and keen-eyed neighbour, friend or uncle. Gilbert White is the centre of the group, and he seems to be setting all the members of it at work on something. He lets drop a hint, asks a question, administers a very gentle reproof, and the recipients of his letters treasure them up, and must, we feel, have acted on them.

One or two points of special interest may be noted here. It is very pleasant to find that Mr. Holt-White has been able to prove conclusively the falsity of the traditional Oriel notion that White retained his fellowship when he should not have done so. The four or five farms which he inherited brought him hardly more than a hundred a year; and towards the end of his life his relations with his College seem to have been quite cordial. It is, of course, natural that in a College where Fellowships were few in number, yet open to competition from the whole University, the locking up of a Fellowship for fifty years should at the time have roused a certain amount of criticism; but that criticism was made under the impression that White was a wealthy man, and to revive it, as it has been revived, in these days, is to do White a serious injustice. The Oriel of that day may be said to have endowed science unconsciously as it has never done since; for White, though not a man of science in the modern sense, has had a powerful influence in stimulating scientific habits.

Among the many delightful treasures in this book must be mentioned the letters of Thomas Mulso, now published for the first time—letters as bright, witty and natural as any that have ever been printed; and the two letters of Montagu, written after the publication of the "Natural History of Selborne," which offer a curious contrast, in their intense and almost feverish ardour, to White's quiet and leisurely way of going about his work. But perhaps those who love the eighteenth century and all its ways will find their greatest pleasure in the enthusiastic diary of Miss Kitty Battie, a visitor at Selborne. Little did that happy girl know that her notes, jotted down in the fulness of a grateful heart, would be treasured more than a century afterwards by readers as enthusiastic as herself.

Let us hope that this work, undertaken by a member of the White family, with full access to all records, and with the invaluable aid of Prof. Alfred Newton, may permanently satisfy all who wish to know about White's character and habits.

The second book mentioned at the head of this notice is a handy little volume in small octavo, which can be carried in the pocket, and has the great merit of being free from unnecessary notes and still more unnecessary illustrations. The few notes which it contains, by Mr. Charles Weekes, are at the end of the volume, and seem to be for the most part accurate and to the point. The text is reprinted from the first edition of the "Natural History," with a few slight alterations in spelling, which might perhaps have been dispensed with. If, for example, White wrote "plowed," there is no reason at all why an editor should substitute "ploughed." And it is a pity that the editor, in prefixing a few lines of Richard Jefferies' to the book, should not have spelt his name correctly. But on the whole the edition is a good one; far better, in fact, than many of much greater pretension.

COSMOGONY AND EVOLUTION.

Entstehen und Vergehen der Welt als Kosmischer Kreizprozess. Auf Grund des pyknotischen Substanzbegriffes. Zweite und erweiterte Auflage. Von. J. G. Vogt. Pp. viii + 1005. (Leipzig: Ernst Wiest, 1901.)

A REVIEWER can scarcely be expected to read the whole of the thousand and odd pages which Herr Vogt has required to express his views on the origin and decay of the world. As one looks down the table of contents, he feels that it would require a mathematician, a chemist, a physicist, a biologist rolled into one to do justice to the many various subjects which here come under notice, and if oppressed with this view he begins with the "methodologische" introduction and struggles with the adjectives, "fearfully and wonderfully made," he may be tempted to turn for a little relaxation to the "explanatory illustrations" scattered through the text. One of these (p. 260) is to explain the genesis of the solar system. The author gives some account of the cosmogony of Kant and Laplace, and recalls some of the objections which have been urged against these views. He is particularly severe on the insufficient explanation offered for the density of the planets closest to the sun. Saturn, he states, retired from the ring-making process when the mass of the ring was 1/118 of its own mass; while in the case of Mercury the sun continued to produce a ring the mass of which is only 1/4,316,550. The evident distaste of Saturn to form rings of smaller mass leads the author to abandon the ring hypothesis altogether and to offer an alternative theory. He conceives spheres of operation (Wirkungssphäre) and Deformierungssysteme (not so easily translated). But if we will imagine three circles, the centres of which form an equilateral triangle and each of the circles touches two others, the circles will form "Deformierungssysteme," while the enclosed triangular space bounded by the three circles is a "field of operation." Now in the small space near the points of contact we get the smaller planets formed, Mercury and the earth on one side and Mars and Venus on the other, each planet touching two circles and the next larger planet. Jupiter in this way has room for his giant bulk, pushing Saturn a little on one side, but otherwise is not inconveniently crowded. Of course, the whole merit of such a cosmogony depends upon the "Deformierungssysteme," and for the manner of working these the reader must be referred to the book itself. The second diagram (p. 949) is to illustrate the precession of the equinoxes. Here one would say there is no room for imagination; we have to do with a problem in rigid dynamics which is susceptible of but one explanation. But if any one thinks this, he has not reckoned with Herr Vogt, who, as a man of ideas, begins at the beginning. Before attempting to explain the cause of any modification in the position of the polar axis it is necessary, he tells us, to understand the laws which determine the constant position of that axis. These laws he proceeds to unfold on "phoronomische" principles, and in his endeavour to follow the author in these same principles the student will be not a little startled to find it necessary to project the plane of the Milky Way on a diagram to explain precession. But he will probably not read beyond the following sentence :—

"The North Pole describes a circle on the sky in about 26,000 years. We can call this circle the projection circle of the absolute orbit of the earth, therefore indirectly the solar orbit, and denote these 26,000 years as the period of the sun in its orbit."

After this one is not surprised to learn that the sun will have a more or less intensive effect on the tension of the æther according to its position in this orbit, and thus to be led to a satisfactory explanation of the phenomenon of the Ice Age.

Herr Vogt is to be congratulated on having found a publisher willing to express these views in a book of handsome appearance, and when one learns that an earlier edition has long been exhausted he is tempted to doubt whether German education is of the elevated character that is sometimes represented. W. E. P.

OUR BOOK SHELF.

The Geological History of the Rivers of East Yorkshire. By F. R. Cowper Reed, M.A., F.G.S. Pp. vi + 103. (London: C. J. Clay and Sons, 1901.) Price 4*s*. net.

SINCE Jukes, some forty years ago, explained how rivers cut through escarpments, the origin of their valleys has been well understood in a general way. Much, however, remained to be learnt about the development of particular rivers and the changes which have brought about present drainage areas; and these subjects have been so attentively and successfully studied by American geologists, notably by Prof. W. M. Davis, that their methods of interpretation have been followed by several observers in this country. The present work by Mr. Cowper Reed gained the Sedgwick Prize Essay for 1890, and is a capital exposition of the evolution of the rivers in East Yorkshire. After giving a general account of the various formations, he points out that the original "constructional surface" on which the present river system was initiated, was a plain formed by the Chalk and other Upper Cretaceous strata, and was upraised in early Tertiary times and perhaps partially eroded during the uplift. Having a greater elevation in the west, the direct ancestors of the present rivers took rise from the higher grounds and flowed eastwards, the Tees and Esk forming one river, the Swale and Ure flowing also direct to the coast, which formerly extended much further eastward, and the Nidd, Wharfe and Aire uniting and flowing out by the Humber. A long period of subaërial denudation followed the initiation of these consequent streams, there was a gradual lowering of the area, and there arose the subsequent river Ouse, which captured the Swale and Ure, the Nidd and Wharfe, conducting their waters into the Humber drainage. Towards the close of the Oligocene period, when the area had been nearly reduced to base-level by the formation of an extensive peneplain and the rivers had attained old age, there was considerable upheaval, accompanied by further movements along pre-Cretaceous lines of flexure, especially in the Moorland range of the Jurassic region. The rivers thereby regained youth and activity, their directions were locally modified, and thus were produced some of the main features in the present topography. Further changes, however, led to other modifications; there was depression towards the close of the Pliocene period, and subsequent elevation in Glacial times. With regard to the Boulder Clay the author judiciously remarks that "the land-ice theory appears to offer fewer difficulties than any others and to explain matters more satisfactorily." In any case large tracts, excepting some of the higher grounds, were buried beneath drift deposits, and the valleys were choked up. When the land had lost its icy mantle, some of these old valleys were revived, but in other cases the streams followed new courses. The story of all these changes is clearly told by Mr. Reed, and although there is room for difference of opinion in matters of detail, the main results are based on fact; and the essay may be profitably studied by those interested in the origin of our scenery.

Fergusson's Surveying Circle and Percentage Tables. By J. C. Fergusson, M.Inst.C.E. Pp. 84. (Published by the Author, 1901.)

THIS is an account of a device intended to replace the dial or circles in magnetic compasses and surveying instruments, with numerous illustrations of its application for the purposes of engineers, surveyors, naval and military officers and travellers. Half of the circle is divided into octants, and the graduation of each octant is effected by dividing its tangent, which is equal to the radius, into 100 equal parts and then drawing lines from these divisions to the centre of the circle. The divisions on the octant thus always subtend equal spaces on an offset laid out at right angles to the quadrantal radius. The spaces on the octant divided in this manner correspond to a hundredth part of the radius, and the angles being read in percentage divisions, trigonometrical formulæ are replaced by simple arithmetic. A considerable simplification of several practical problems is suggested by the examples given, but the advantages of the method can scarcely be judged without actual experience. It is stated, however, that many distinguished engineers and surveyors have expressed complimentary opinions as to its merits. Messrs. T. Cooke and Sons are the manufacturers of the new circle, which can be adapted to old or new instruments.

How to Know the Indian Ducks. By F. Finn. Pp. iv+101. (Calcutta: Thacker, Spink and Co., 1901.)

IF the right to include under the name of "ducks" both geese and swans be conceded to the author (and we have some doubt whether it should be), we have nothing but commendation for this excellent little volume. Years ago, when duck-shooting on the Ganges, we have a vivid recollection of our own regret at being unable to identify all the various representatives of the duck tribe included in our "bag," and we have little doubt that this regret has often been shared by other sportsmen. For the future, however, there should be no difficulty whatever in determining the species of any member of the tribe which may fall to the gun of the sportsman in India, as Mr. Finn's volume is small enough to be carried in the pocket without inconvenience, while the lowness of its price brings it within reach of every one. Needless to say, as the author is an accomplished ornithologist who has devoted special attention to the Indian Anatidæ, the descriptions are all that can be desired from a scientific point of view, while the simple language in which they are written, and the useful "keys" for the identification of species, render the volume admirably adapted to the needs of sportsmen.

It is for this class, indeed, that the work is primarily intended, as the author tells us in his preface; and the fact that the substance of the text has already appeared in the form of a series of articles in the columns of the *Asian* newspaper bears testimony to its favourable reception by Anglo-Indian sportsmen.

On more than one occasion we have directed attention in these columns to the confusion caused by the diverse systems of nomenclature followed by ornithological writers. In the present instance we are glad to see that the author endeavours to promote uniformity in this respect by following the classification and nomenclature adopted by Mr. W. T. Blanford in the "Fauna of British India." R. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Determination of Positions in Polar Exploration.

HAVING in view the importance of this subject in connection with the forthcoming Antarctic expedition, a brief comment on the results obtained in high latitudes, with which we have been favoured during the last few months, may not be out of place. The publication of the scientific results of the Nansen expedition is now before us, and these, together with a few which (without further explanation perhaps) scarcely merit the employment of this adjective, and which are to be found in the pages of Mr. Borchgrevink's account of the *Southern Cross* expedition, afford food for reflection, but whether they could be more satisfactorily dealt with by a professional man of science or a professional humorist may be open to question. The first have resulted in a series of deductions and suggestions which will strike thoughtful men as being eminently unpractical, and the latter is responsible for considerable confusion of mind in regard to the geographical positions of the most important points to which the expedition just about to start is instructed to proceed.

These being for the moment the more important, may be dealt with first. It has already been pointed out by NATURE that the recorded observations of the Borchgrevink expedition are extremely unsatisfactory, owing, possibly, to the work of a copyist ignorant of nautical calculations, but besides being improperly copied they are improperly computed. One, owing to the use of the secant of an erroneous latitude, is made to produce a longitude 22′ in error. Another computes the declination with a correction for longitude instead of for the Greenwich date. A third professes to find the chronometer error to a couple of seconds by a lunar eclipse (a feat which, if true, is miraculous); and a fourth produces a longitude of the harbour under the great ice barrier from which Mr. Borchgrevink effected his landing which is said by the navigating officer to be 164° 32′ W., by the commander 164° 10′ W., and by the president of the Royal Geographical Society 162° 30′ W.

The position of Cape Adare, again, is of the very first importance. Ross placed it in 71° 18′ S.; Mr. Borchgrevink finds this latitude correct, but places it 36′ further to the East; while Sir C. Markham, if we may judge by the *Geographical Journal* for July, has apparently been informed that it lies in lat. 71° 30′ S.

Much satisfaction has been expressed at the supposed verification of the position of two groups of islands (the Balleney groups), but much astonishment has also been expressed by thinking men that the Geographical Society can attach the faintest importance to the determination either of their number or their position by officers who, in discussing the subject, contradict each other flatly both as to the date, the appearance and the distance of the land at the time of the discovery; to say nothing of the suggestion that at distances ranging from 90 to 40 miles abundance of detail, including crevasses, and the shore line were plainly visible.

Turning to the scientific results of the Nansen expedition, and having in view the remark of your reviewer (NATURE, June 13), that the volume is to be welcomed as exceedingly opportune in view of the approaching Antarctic expedition, I should like to call the attention of the scientific staff to certain information which they may find it interesting to put to a practical test. It is here suggested:—

(1) That the value of refraction can be estimated from astronomical observations taken during a drift, when the latitude by which the altitudes are computed depends upon the unknown refraction and the refraction upon the unknown latitude. (See table of refractions).

(2) That the altitudes necessary for the computation of a lunar distance can be calculated by a man having no knowledge of his Greenwich time and being uncertain of his longitude to the extent of from 15 to 25 degrees. (See Nansen's lunar, taken August 10, 1895).

(3) That the discrepancy between two sets of altitudes taken, the one with a glass horizon labouring under suspicion and the

other with a pocket sextant and ice horizon, justify the conclusion that the terrestrial refraction was so abnormal, that the computation of the latitude necessitated the reversal of the sign of the dip; but that this state of things was local, and that the observations of another observer only ninety miles away would not be so affected, though the temperature and general conditions were in both cases practically the same. (See comparison between the corrections for refraction in the meridian altitudes of Nansen at his Farthest North, and Hansen on board the *Fram*, April 6, 1895).

Admitting to the full the truth and justice of the remark of your reviewer in connection with the observations taken during Nansen's sledge expedition, that "the fact that observations were taken at all is the strongest possible evidence that scientific zeal is compatible with the possession of remarkable courage," it must also be admitted that a comparison of these scientific results with those which Nansen obtained from the same times and altitudes proves that scientific zeal and the power of taking observations are also compatible with the inability to comprehend the very elementary fact that if the results of two or more observations differ widely from each other neither is trustworthy, and that geographical positions and condemnations of the work of such men as Julius Payer and Wyprecht cannot, and ought not, to be based upon them.

Should any student of practical nautical astronomy go to the trouble of making this comparison, he cannot, I think, fail to perceive at every step that, however painstaking Prof. Geelmuyden and his colleagues have been in their attempt to plot Nansen's route on his celebrated sledge journey, they have been compelled to ignore his own statements and his own workings, and while straining at the scientific gnat they have freely swallowed the practical camel. Dr. Nansen had led us to believe that the scientific results would explain and justify his already published results. It can be easily shown that one or the other is hopelessly wrong. They are totally irreconcilable. If it is for one moment admitted that Nansen had the opportunity and ability to work the common observation for longitude by chronometer, then Prof. Geelmuyden's primary hypothesis is unsound. If it is maintained that that hypothesis is even approximately correct, Nansen's own recorded results become ridiculous.

Turning from matters of fact to matters of opinion, two statements of great interest to explorers in high latitudes may be noticed. On p. 14 we are informed that one of the computers employed with advantage the difference of altitude near the prime vertical to determine the latitude. Now in low latitudes, where the change of altitude is rapid, say from 10′ to 15′ per minute of time, a result within five or ten miles of the truth is perfectly possible. In latitudes from 70° to 85° N., with altitudes changing at most 5′ or 6′ per minute of time, and affected by refraction abnormal in itself, and varying rapidly according to no well-defined law, the method entirely fails. If a chance observation appears to justify its use, the altitudes must be accidentally or miraculously correct.

The remark on lunars, p. 22, will strike experienced observers as exceedingly curious. "The results," says Prof. Geelmuyden, "are not satisfactory."

Table C., p. 44, shows that eight observations were taken at various times, and from them Greenwich Mean Time was determined with errors varying from 18 seconds to 2 minutes. On the assumption that the explorers might have been dependent on them, their positions would have been affected with a maximum error of 30′ of longitude, or about four geographical miles. Let future explorers note this. It may safely be affirmed that these results will seldom be surpassed by men taking lunars under Arctic conditions. It may with equal truth be said that for the purposes of such explorers greater accuracy is unnecessary; and the submission to a practical test of Prof. Geelmuyden's opinion, that better results can be obtained by deducing the moon's right ascension from the difference of azimuth of the moon and a star, will be a task not unworthy of the scientific expert accompanying the *Discovery*. E. PLUMSTEAD.

"First on the Antarctic Continent."

SOME rather venomous criticism of my book, "First on the Antarctic Continent," has appeared in one or two periodicals. Had my book been intended to be what it is not—a scientific report upon our work in the south—the venom would to some extent be justified. There are, however, other circumstances which prevented me from producing at the time a larger and more representative account of our work in the south. Preliminarily may I state that the observations have been submitted to the Council of the Royal Society, who have accepted them, and the Society is in due time going to publish a volume on the results? This speaks for itself of the efficiency of the staff I had chosen. The Natural History Museum of South Kensington has received the bulk of the collections and I understand that the report upon them is nearly finished, and the book, written by specialists of the Museum, will probably appear within a very short time. C. E. BORCHGREVINK.

(Commander, British Antarctic Expedition, 1898–1900).

Douglas Lodge, Bromley, Kent, July 5.

The Settlement of Solid Matter in Fresh and Salt Water.

IN a letter under the above heading in your issue of June 20, Mr. W. H. Wheeler discusses the effect of dissolved salt in promoting the subsidence of alluvial matter in water. He takes exception to the conclusion of Mr. Slidell that the mixture of sea water with river water exercises a preponderating influence on the formation of deltas. The question at issue is not one that can be settled simply by a consideration of the specific gravity and viscosity of the solutions employed, and Mr. Wheeler has made it the subject of experimental investigation. There can be little doubt that it is only in the case of very finely divided solid matter in suspension that the addition of salt solution causes increased precipitation, and so far his results can scarcely be called into question. They are confirmed by the investigations on the deposition of sediment by Carl Barus and Bodländer, to whose papers references are given below.

The precipitation of such "suspensions" or "pseudo-solutions" by the addition of an electrolyte is accompanied by the coagulation or flocculation of the solid matter. Schlœsing states that clay suspensions pass through a filter paper, but can easily be filtered if coagulated by a salt solution. If, however, the clay is washed free from salt, it can enter into suspension again in pure water and be precipitated afresh. These two operations can be performed in succession several times without apparent modification in the results. Picton and Linder found that the coagulum produced by the precipitation of a pseudo-solution of arsenic sulphide contained traces of the metallic ion, which could not be removed by washing.

The mud or ooze examined by Mr. Wheeler seems to have consisted entirely of matter which had already undergone precipitation, but it does not appear from his letter that any precautions were taken to remove traces of the metallic salts, so that it remains doubtful whether the sample really formed a suspension in the pure water. More satisfactory experiments could perhaps be made by collecting samples of turbid water from a river in flood and then adding sea water or a solution of salt.

I had occasion some time ago to consult the somewhat extensive literature dealing with the suspension of solid matter in a fluid and the allied one of colloidal solutions, and the following list of papers, though doubtless far from complete, may be of use to some readers of NATURE:—

Skey, *Chem. News*, xvii. p. 160; Waldie, *Chem. News*, July 24, 1874; *Journ. As. Soc. Bengal*, 1873; Th. Scheerer, *Pogg. Ann.*, lxxxii. p. 419, 1851, einige Beobachtungen über das absetzen auf geschwemmter pulverförmiger Körper in Flussigkeiten; Hunt, *Proc. Bost. Soc. Nat. Hist.*, pp. 302–4, 1874; Slidell, *Report* of Messrs. Humphreys and Abbott on the physics and hydraulics of the Mississippi, App. A, p. 11, 1861; Ch. Schlœsing, *Compt. rend.*, lxx. p. 1345, 1870, sur la précipitation des limons par des solutions salines très-étendues; David Robertson, Glasgow Geol. Soc. *Trans.*, iv. pp. 257–9, 1874; W. The Teaching of Mathematics.

BEING myself a teacher of mathematics, I have followed with much interest the vigorous crusade against the neglect of suitable scientific and mathematical training conducted by Prof. Perry and others, and am in substantial agreement with Prof. Minchin's remarks in his review in your columns of the series of papers by Prof. Perry on "England's Neglect of Science."

One thing has struck me in connection with school "mathematical" teaching as being a very illogical course of procedure on the part of the dominant "classical cleric" instructors of youth alluded to—namely, the teaching of *arithmetic*. A boy, whether classically or otherwise educated, is considered a dunce if he is not merely not an expert with the multiplication table, but even if he is unacquainted with such things as recurring decimals, square and cube roots, &c., whereas no attempt is generally made to give an insight into *theory*, the results, *i.e.* the *rules*, are what he is expected to know.

So dissociated to the ordinary mind is the science of arithmetic from mathematics that I can remember a fellow collegian actually remarking, "Mathematicians are bad at arithmetic"! It seems to me, on the other hand, that Euclid is much more out of the line of what we mean by mathematics. In teaching Euclid as a mathematical "subject," and, as some claim, as an introduction to geometry, we are actually raising barriers to the progress of a learner in grasping the meaning and uses of geometry. We insist on the propositions being learned *in all their cases*, insisting on the absolute distinctness of propositions which are merely particular cases of the same proposition, thus tacitly suggesting the existence of some such commandment as "Thou shalt not recognise the Principle of Continuity"—we ignore the infinite and we teach to try and wriggle away from the notion of a "limit." In fact, nearly all that really constitutes mathematics is carefully avoided in teaching of Euclid, whereas I have found, when I have dared once or twice to depart from examination ideals, how true the following remarks of Mr. C. Taylor in his prolegomena to "The Introduction to the Ancient and Modern Geometry of Conics" are. When referring to the work of Boscovich, he says:—"It is remarkable that Boscovich enters upon these abstruse speculations in an elementary treatise for beginners.... The preface to the volume contains an earnest plea for the introduction of the modern ideas into the schools. He had taught the appendix *viva voce* to his own tyros with the happiest results .... demonstrations are put before him (the tyro) in an unsuggestive form which gives no play to his inventive faculty; and thus it comes to pass that of the many students so few turn out genuine geometers ..."

I must not encroach further on your valuable space, although many points come to one's mind, such as the exclusion from so-called "higher algebra" papers of the theory of determinants, arithmetic without logarithms, applied mathematics without the calculus, &c., but, in hopes that the attack may be vigorously pushed home, subscribe myself yours sincerely,

Henry Smith School, Hartlepool. F. L. WARD.

Curious Rain drops.

ON Thursday last, July 11, about 6 p.m., the day having been sultry, the sky became dark and overcast, threatening rain. Only a few scattered drops fell, however (the threatened rain passing off), but these sparse rain-drops drew my attention by their curious appearance on the sill of the window near which I sat.

Each rain-drop had broken up into a number of smaller drops, which arranged themselves in a circular form around a central one, in the manner here shown 
Perhaps some one of your readers would kindly explain the cause of this, and if it was due to some electrical condition of the atmosphere. M. S.

Bowdon, Cheshire, July 14.

THE MYCENÆAN QUESTION.[1]

THE occasion for the following remarks on that difficult and much disputed subject, the Mycenæan Question, is furnished by the appearance of the timely volume on the "Oldest Civilization of Greece," by Mr. H. R. Hall, of the British Museum, and as public interest in the whole question has been considerably quickened by the important discoveries of Mr. A. J. Evans in Crete, this book, in which certain of the principal results of the Cretan excavations are discussed, will be heartily welcomed by the broad-minded school of classical archæologists in general, and by the student of ancient Oriental civilisations in particular.

It is now some twenty-five years since the spade of Schliemann brought to light the remains of the oldest civilisation of Greece; and as it was soon recognised that these remains belonged to the period of the Bronze Age, it was clear that they must be older than the classical period of Greek culture. The excavations which were made subsequently in several parts of the Greek world by the various investigators who were emulating

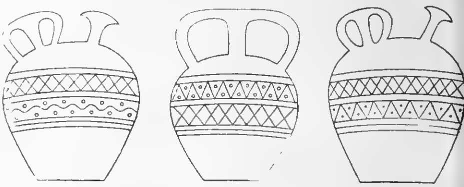

FIG. 1.—Representation of Mycenæan vases; from a fresco in the tomb of King Rameses III. at Thebes, B.C. 1200.

Schliemann's example proved that this Bronze Age culture was not confined to any particular part of Greece, but extended over the whole Hellenic area. Such discoveries compelled classical scholars to abandon many preconceived notions, and they found it necessary to revise entirely their ideas about the origins of Greek civilisation; it is not to be wondered at that many excellent scholars of the "old school" still find it difficult to make their views fall into line with the new order of things in classical archæology. This is most evident when the dating of Mycenæan antiquities has to be considered, for if the Mycenæan culture, being of the Bronze Age, is necessarily pre-classical, its *floreat* must be assigned to the second millennium before Christ. An important confirmation of this view seems to be supplied by the evidence derived from the excavations which have been made in Egypt in recent years, where a large number of objects, pottery, &c., of Mycenæan origin have been found; and in many cases such objects have been discovered side by side with native Egyptian objects which must belong to the period which lies between B.C. 1500 and B.C. 1000. The discoveries of Mr. A. J. Evans, however, all seem to point to a still earlier date for the first development of

1 "The Oldest Civilization of Greece: Studies of the Mycenæan Age." By H. R. Hall, M.A., Assistant in the Department of Egyptian and Assyrian Antiquities, British Museum. Pp. xxxiv + 346; with 76 illustrations. (London: D. Nutt, 1901.) Price 15*s*. net.

Mycenæan culture out of primitive barbarism, and a useful indication of its antiquity is supplied by the discovery, recently announced, of a statue of King Khian of Egypt, in Crete. Now the existence of King Khian was made known to us by numerous scarabs and certain monuments which were found at Tanis in the Delta and Baghdad in Turkey-in-Asia, and it is generally thought that he was a Hyksos king, who reigned about B.C. 1800. Prof. Petrie, judging from the style of the work on Khian's scarabs alone, has assigned this king to a far earlier date, *i.e.* to the period between the sixth and eleventh dynasties, about B.C. 3000; there is, however, no sufficient foundation for this view, and, so far as we know, it is not accepted by the majority of Egyptologists. The discovery of Khian's statue by Mr. A. J. Evans in the Mycenæan Palace of Knossos takes its place naturally in the long series of facts derived from archæological evidence collected in Egypt and Crete, which point with one accord to a date before B.C. 1500 for the beginnings of the Mycenæan period properly so-called.

FIG. 2.—Egyptian vase imitating Mycenæan form, about B.C. 1350. (British Museum.)

The first systematic arrangement of the evidence which was derived from the discoveries of Schliemann was embodied in the work "Mykenische Vasen," by Messrs. Furtwängler and Löschcke, to whom the classification of Mycenæan pottery is due, and an anticipation of the conclusions to which Mr. A. J. Evans' discoveries appear to tend in respect of the prominent part which the Cretans took in the early Greek civilisation was essayed by Dr. Milchhoefer, whose "Anfänge der Kunst in Griechenland" appeared about the same time. The position which Mycenæan archæology had reached about 1890 was well summed up in Dr. Schuchhardt's epitome of Schliemann's works, and in this book we already see the beginnings of an attempt to obtain accurate dates for the periods of the Mycenæan culture by means of conclusions drawn from results supplied by Egyptian excavations. Many of the available data employed by Dr. Schuchhardt and his successors were supplied by the excavations of Prof. Petrie at Kahun and Gurob, and above all at Tell el-Amarna, from which site conclusive evidence of the contemporaneity of Mycenæan culture with the heretic king Amen-hetep IV. and other monarchs of his dynasty can, *pace* Mr. Cecil Torr, be deduced.

But about this time attention began to be drawn to the remains of a pre-Mycenæan period of culture in Greece, and the discoveries of Prof. Dörpfeld at Troy resulted in a definite arrangement of the prehistoric civilisation of Greece in two well-defined periods, viz. the primitive or pre-Mycenæan, and the fully developed or Mycenæan Ages. The arrangement made by Dr. Dörpfeld became, in its turn, the base of a general sketch of Mycenæan archæology in the Mycenæan Age which was published in 1897 by Prof. Tsountas and Mr. Manatt, a work which, though based on Prof. Tsountas's earlier essay, was thoroughly revised and brought up to date in the light of the most recent research. This book, however, has one cardinal defect, and the evil effects of this defect are far-reaching: Prof. Tsountas, having arrived at certain conclusions, which from the nature of the case must be of a hypothetical character, states them as so many concrete facts instead of giving the reader to understand clearly that they are only his own opinions. Since

FIG. 3.—Bügelkanne of Mycenæan type made in Egypt, B.C. 1350. (British Museum.)

the publication of this book, however, Mycenæan archæology has entered upon a new phase, owing to the discoveries made by the British School at Athens on the site called Phylákopi, in Melos, and by Mr. A. J. Evans at Kephala, the site of the ancient Knossos in Crete, which have produced a mass of new and highly suggestive material for the archæologist to work upon; the results obtained from these excavations tend to indicate a comparatively high antiquity, *i.e.* about B.C. 1500, for the period when Mycenæan culture had attained its highest development. A different conclusion, however, seems to have been indicated as the result of the excavations which were carried out at Curium and Enkomi by Dr. A. S. Murray, of the British Museum, and his assistants, Mr. H. B. Walters and Mr. T. L. Myres, for the general evidence derived from the objects which they found in the course of their work shows that Cyprus continued to be included within the circle of Mycenæan culture as late as the ninth and eighth centuries before Christ. This date agrees with that assigned by Mr. A. J. Evans to the late Mycenæan treasure from Aegina which is now in the British Museum.

It has been necessary to make the above somewhat lengthy chronological statement on the Mycenæan question in order that the reader may be able to understand the exact position which Mr. H. R. Hall takes up on this disputed ground of research. He divides his work into eight chapters, which discuss the new chapter of Greek history generally, and the relation between the archæologist and historian in the elucidation of Mycenæan antiquities; the generally accepted Mycenæan hypothesis as modified by the latest discoveries; the questions of date and race; Mycenæ and the East and Mycenæ and Egypt; Mycenæ's place in history, including a discussion on the period of the introduction of the metals into Europe; and the decadence and renascence of Greek culture after the close of the Mycenæan period. The book contains in addition four appendices, seventy-six illustrations, full indices, notes, &c. Many of the facts which are given in Mr. Hall's book are familiar to us from other sources, but he has brought forward from the domain of Egyptology a considerable number which will probably be new to the majority of his readers; indeed, if we remember rightly, the Mycenæan Question has never before been handled by one whose training has made him familiar with both Greek and Egyptian archæology. His chapter, then, on the connection between Mycenæ and Egypt will be read with much interest, especially his remarks of the identifications of the northern Mycenæan tribes who attacked Egypt between B.C. 1400 and B.C. 1150. He has identified the tribe of the Uashasha with the Axians of Crete, and he has shown the probability that others of the tribes which are mentioned in Egyptian history at this period

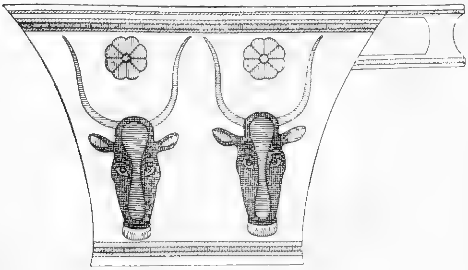

FIG. 4.—Representation of a Mycenæan metal vase from the tomb of Rekh-ma-Rā at Thebes, B.C. 1550.

were of Cretan origin, including the Pulesatha, or Philistines.

It has been noticed that many of the names of these tribes ended in "sha" or "na," and Mr. Hall has, with apparently very good grounds, identified these terminations with the common nominal suffixes "azi" and "ñna" which are found in the Lycian language and, seemingly, also in other cognate speeches of Asia Minor. Mr. Hall seems also to have devoted his energies to the solution of the difficult problem of dating the early antiquities of Greece, and, so far as we understand him, he takes in this respect a position midway between those who hold that the latest date possible in Mycenæan archæology is B.C. 1100 and those who hold, with Dr. A. S. Murray, that this date is more likely to be the *earliest* which can be assigned to Mycenæan antiquities, *i.e.* he believes that in Greece proper and in Crete the Mycenæan culture began at a very early period—which, however, he does not define exactly—and had already reached its highest pitch of development about B.C. 1500, when its chief seat was in Crete, and when it was extending its influence to Egypt and Asia Minor. He considers that the discrepancy between the two extreme views can be reconciled on the theory that in Greece proper the Mycenæan age came to an end about B.C. 1000, but continued to exist in Asia Minor until about B.C. 800, and in Cyprus until a century later.

This view is perhaps confirmed by the fact that the Dorians, who, *ex hypothesi*, overthrew the Mycenæan culture in Greece, did not reach Asia until about B.C. 800, and never gained any foothold whatever in Cyprus. Another important point made by Mr. Hall is that, contrary to the usually accepted view, iron was already known to the Egyptians about B.C. 3500, when, as he says (see p. 198), "it appears named and depicted on the monuments in a manner which admits of no possibility of doubt as to its nature." He supports his statements by quotations from a learned article by the Swedish Egyptologist, Prof. Piehl, which appeared in *Ymer* (1888, p. 94 ff.), from which it may be safely concluded that the Egyptians were acquainted with the use of iron some 2500 years before it came into general use in Europe. We notice that the passages which Mr. Hall quotes from Egyptian texts are translated by him especially for the purposes of this book, and he weighs with discretion the evidence which many would derive from the cuneiform and from the so-called "Hittite" inscriptions for the elucidation of the origins of Mycenæan culture. It is interesting to note that he believes it possible that the system of writing which was in use among the Cretans may have been derived from the Egyptian hieratic, and he points out some probable instances of the similarity between the two scripts; but, contrary to the opinion expressed by Mr. A. J. Evans,

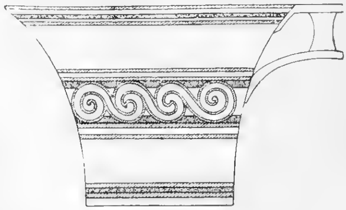

FIG. 5.—Representation of a Mycenæan metal vase from the tomb of Rekh-ma-Rā at Thebes, B.C. 1550.

he thinks that the writing is to be read from right to left, because the figures of men, birds, &c., which occur in it invariably face to the right, and should, on the analogy of Egyptian, face the beginning of the line (see p. 141). Still, it must not be forgotten that, chiefly owing to geographical difficulties, there cannot have been much direct communication between Crete and Egypt across the open sea in the Mycenæan period, and the connection between the two countries must have been carried out *viâ* Cyprus and the coast of Palestine; and it is a fact that the Cretan and other northern marauders who attacked Egypt in the reigns of Menephthah and Rameses III. made their way to Egypt by this route.

There are many other points of interest in the book to which we should like to draw attention, but our space is exhausted. The Mycenæan question is a difficult one, and one which, in our opinion, will not be settled for some years to come; the evidence which will bring about this result is accumulating, but there is not enough of it available yet. The most serious phase of the question as it now presents itself is the discrepancy between the dates assigned by experts for the beginning and end of the period of Mycenæan culture proper. Mr. Hall does not claim, if we understand him aright, to have settled this difficulty, but there is no doubt that he has collected a number of facts which will one day form valuable elements in the solution of the problem, and he has set forth the Egyptian aspect of the Mycenæan question in a clearer form than any of his predecessors. His volume contains an excellent summary of the work already done, and will give the reader a capital idea of the position of the workers in the Mycenæan field; it will also enable him to take an intelligent interest in the labours of future workers and to appreciate the developments of a most fascinating line of research.

THE SOUTH EASTERN AGRICULTURAL COLLEGE AT WYE.

THE new block of buildings just completed at the South Eastern Agricultural College at Wye, Kent, is to be opened by the Right Hon. R. W. Hanbury, president of the Board of Agriculture, as we go to press this week. As the College has been constituted a school of the University of London in Agriculture, it may be of interest to give a short account of this institution—one of the most advanced examples of the development of agricultural education under the administration of "the whisky money" by county councils.

The College began work in 1895, and is managed under a scheme of the Charity Commissioners by a governing body appointed by the county councils of Kent and Surrey, together with representatives of the Universities of Oxford, Cambridge and London, the Royal and the Bath and West Agricultural Societies. The buildings, which are situated at Wye, a little village on the South-Eastern line between Ashford and Canterbury, consist of a nucleus built about 1470, an ancient collegiate foundation due to the Cardinal Archbishop Kempe, with successive additions made in 1894 and the current year.

The old buildings form a small quadrangle with brick cloisters and include a fine and lofty hall, the refectory of the original College now restored to its original purpose, and a beautiful oak panelled room, which is used as the library. The later additions form a second quadrangle, with lecture rooms, &c., on the ground floor and students' living rooms on the first floor; the chemical laboratories occupy a further wing. There are two lecture rooms, one a theatre with raised seats accommodating 150 people; the drawing office provides working space for twenty-four students in such subjects as surveying, building construction and farm engineering. On the biological side there is a laboratory with working space for thirty students, furnished with Swift's histological microscopes; two smaller laboratories for the professors of botany and economic entomology, and a museum, of which the chief features at present are a collection illustrating the insect pests attacking fruit and hops, specimens illustrating the forestry course, pathological specimens in connection with farm animals, typical cereals, soils, &c.

FIG. 1.—Chemical Laboratory of the South Eastern Agricultural College.

The chemical laboratories consist of a general students' laboratory, measuring about 45 by 30 feet, lighted on both of the longer sides of the room; it is fitted with two double benches running longitudinally, reagent bottles being carried on glass shelves down the middle of the tables. The two benches give working room for thirty students, and other benches in the window recesses are provided for special work; water and gas are laid on to all the tables, and there are two fume chambers within and one outside the laboratory. Separated from the main laboratory by a glazed partition is the balance room and the larger of the analytical laboratories; adjoining this comes a smaller room reserved for gas analysis, titrations, &c., that require an acid or ammonia free atmosphere, and next to this comes a room for the furnaces and for ether extractions and other operations involving the use of inflammable liquids; in one corner of this room a drying chamber has been built.

The College farms about 250 acres of and adjoining it is preeminently a sheep farm, the soil being a light loam resting on chalk; the main features of the farming consist of a breeding flock of the Romney Marsh breed, a small dairy herd of shorthorns and a large stock of poultry. There is a small hop garden, planted in 1895, to test the various systems in vogue of training hops and for other experimental work. The two fruit plantations are both young; one is used for teaching purposes, the other is mainly laid out for experiments. On the farm are situated the dairy, forge, carpenter's shop, apiary, &c.

The staff of the College consists of seven resident professors and lecturers, together with instructors in practical subjects, demonstrators, &c., the necessity for this extensive staff being that the College is also a centre for much practical experience with the children of the Wye Elementary School.

At present there are some fifty to sixty students in residence, mostly taking the ordinary course, but a few are doing special work in the laboratories; it is hoped that such students will increase with the facilities the institution now affords for research which requires work both in the field and the laboratory. Both at home and in our Colonies and dependencies agriculture wants trained investigators and teachers if we are to keep our place, and the South Eastern Agricultural College is making a serious attempt to supply within the London University the kind of institution that has done such good service for American and German farming.

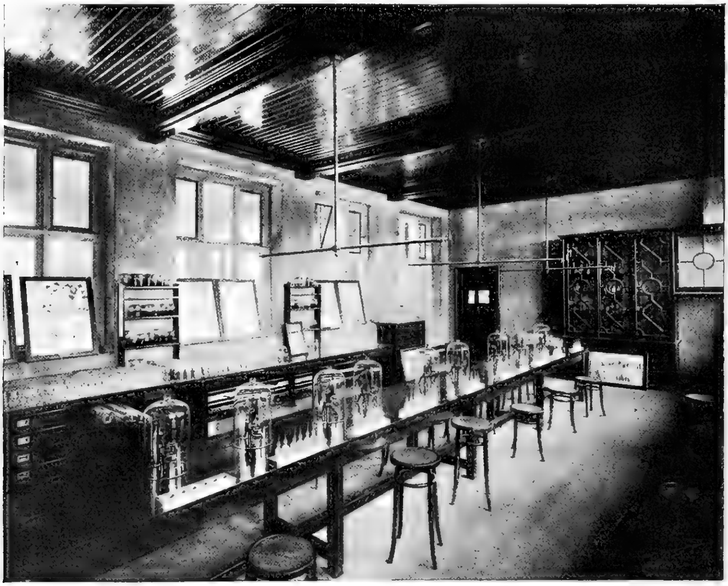

FIG. 2.—Biological Laboratory of the South Eastern Agricultural College.

extra-mural work in the counties of Kent and Surrey, such as courses of lectures, analyses of soils and manures, reports on crop diseases, field experiments and similar investigations. As regards the latter, experiments on the manuring and cultivation of hops have been carried on consecutively for six years, and results of considerable practical importance are beginning to emerge. Other work extending over several years has been done on the quality of barley as affected by manuring, the cost of growing sugar beet and its food value, and a systematic examination of the soils of Kent and Surrey has also been in progress for some time.

The normal course of instruction extends over two or three years; the College grants a diploma of its own, and with the constitution of a board of agricultural studies in the University of London it is expected that regulations for the degree course will soon be forthcoming.

Short sessions for special purposes are held from time to time; in August, for example, there will be a normal course of instruction in "nature knowledge" for elementary school masters, the outcome of two years'

THE BRITISH ASSOCIATION.

GLASGOW MEETING, SEPTEMBER 11-18, 1901.

IN the first article which appeared in NATURE on May 23, particulars were given regarding the local arrangements as to reception room, rooms for sectional meetings, and the halls in which the presidential and other evening scientific lectures were to be delivered. The Friday evening lecture is to be given by Prof. W. Ramsay, on inert constituents of the atmosphere, and the Monday evening lecture is to be given by Mr. Francis Darwin, on the movements of plants.

Two important fixtures by the Excursions' and Entertainments' Committee have been made since the last notice, namely, the chartering of one of the Clyde steamers for a whole day's sail on Saturday, September 14, and the acceptance of an offer by Lord Blythswood, president of the Philosophical Society of Glasgow, to give a garden party in the Botanical Gardens on the afternoon of Monday, September 16.

Promises of numerous papers by eminent authors are already received by the recorders of the different sections. Indeed, one or two of the sections generally get more papers than is necessary to fill the time of the sittings. For example, Section A not only meets on Saturday, but is also on two days actually divided into two subsections. On Friday it is to be divided into (1) physics, and (2) astronomy. On Monday it is to be divided into (1) mathematics, and (2) meteorology.

At this early stage a full and definite programme of the different sections cannot be given. But the following brief provisional programme may be taken as conclusively indicating that the meeting promises to be a most successful one from an educational and scientific point of view.

Section A (Mathematical and Physical Science).—A large number of papers are already promised for this section. The following may be mentioned:—Five papers, dealing with elasticity, viscosity, magnetic fields, and stress and magnetisation of nickel and cobalt, are promised from the physical laboratory of the University of Glasgow by Prof. Gray, his assistants and the research students in his department. Dr. Larmor will give a paper on radiation, Dr. Hicks a paper on the Michelson-Morley effect and Dr. Glazebrook a paper on optical glass. In the meteorological department, Mr. W. N. Shaw and one of his assistants will give two papers treating of the seasonal variations of air temperature.

Section B (Chemistry).—The following papers have already been promised:—On the transitional forms between crystalloids and colloids, by Messrs. J. H. Gladstone and W. Hibbert; the oxidation of tin, including the action of light, by Messrs. J. H. Gladstone and G. Gladstone. Papers on the following subjects will also be submitted:—On the deposition of ocean salts, on electrochemical processes and on the manufacture of cyanides.

Section C (Geology).—Papers to this section are promised by Messrs. William Gunn, B. N. Peach, R. H. Traquair, Robert Kidston and H. B. Woodward. Several others have intimated a wish to read short papers on subjects in which they are specially interested.

Section G (Engineering).—A paper on the mechanical exhibits at the Glasgow International Exhibition is being arranged for. After a report on road traction is submitted by a committee appointed for the purpose, papers bearing on this subject will be read by Messrs. A. R. Sennett, A. H. Gibbings and Sir J. H. A. Macdonald. The following papers will also be given to this section:—Protection of buildings from lightning, by Mr. K. Hedges; dielectric hysteresis, by Mr. W. M. Mordey; Panama Canal, by Mr. M. Buon Varilla; tunnelling in quicksand, by Mr. M. A. Gobert; chain driving, by Mr. C. Garran; engraving machinery, by Mr. M. Barr; and aluminium as a fuel, by Sir W. C. Roberts-Austen. Mr. Barr will probably show his apparatus working in the municipal buildings during the evening of Thursday, September 12.

Section K (Botany).—There will be a discussion in this section on the teaching of botany, opened by Mr. Wager from the standpoint of botany teaching in schools, and by Prof. Bower from the point of view of University teaching. Profs. Ward, Scott-Elliott, Miall and others will take part in the discussion. It is intended to ask members of Section L, the educational section, to take a share in the discussion. Prof. Reynolds Green will probably give a semi-popular lecture on a botanical subject of general interest.

Section L (Educational Science).—After the president, Sir John E. Gorst, delivers his presidential address, it is expected there will be a discussion on Scottish educational systems. This discussion will probably be introduced by two papers, one by Mr. John Adams, on mechanism of education in Scotland, and the second by Dr. J. G. Kerr, on the training of the practical person.

On account of the International Exhibition there is a great influx of visitors to Glasgow, and members of the British Association who intend to be present at the Glasgow meeting are strongly recommended to make early arrangements for their rooms. The local committee have prepared a list of hotels and a preliminary list of lodgings and apartments. This list is ready to be sent to any inquirer. MAGNUS MACLEAN.

NOTES.

PROF. A. W. RÜCKER, professor of physics at the Royal College of Science and secretary of the Royal Society, has been appointed principal of the University of London. We are informed that, in consequence of his appointment to this post, Prof. Rücker will resign the secretaryship of the Royal Society at the next anniversary meeting.

PROF. VIRCHOW'S eightieth birthday will be celebrated in Berlin on Saturday, October 12, when he will personally receive delegates with congratulatory addresses from various scientific bodies, foreign as well as German. Prof. Waldeyer is the president of the executive committee.

THE Council of the Royal Society has awarded the Mackinnon studentship to Mr. J. J. R. Macleod, demonstrator of physiology in the London Hospital Medical College, for the purpose of enabling him to carry out researches in pathological chemistry. The studentship is founded under a bequest to the Royal Society by the late Sir William Mackinnon, Director-General of the Medical Department of the Army, for the foundation and endowment of prizes or scholarships for the special purpose of furthering natural and physical science, and of furthering original research and investigation in pathology. The studentship, for which fourteen applications were received, is of the annual value of 150*l*.

THE death is announced of Mr. J. Hamblin Smith, the well-known mathematical coach at Cambridge and author of numerous successful text-books of elementary mathematics. Mr. Smith was seventy-four years of age.

PROF. PASQUALE VILLARI has been elected president of the Reale Accademia dei Lincei, of Rome, in succession to the late Prof. Messedaglia.

AN excursion to the Auvergne district has been arranged by the Geologists' Association. The party will leave London on the evening of Thursday, August 15, and will journey to Clermont, which will be the centre of the excursions. The visit will last a fortnight, and an excellent programme has been arranged under the direction of Prof. Marcellin Boule, Prof. P. Glangeaud and M. J. Giraud.

A TELEGRAM from Ponta Delgada to the *Times* states that the International Meteorological Observatory in the Azores was inaugurated on July 10 by the King of Portugal. The Portuguese Prime Minister, the Minister of Marine, the civil governor of the islands and the different authorities, together with a number of Portuguese officers and the officers of the British cruisers *Australia* and *Severn*, were present at the ceremony.

WE are sorry to learn that the biological station which had been kept on Lake Baikal for a year by the East Siberian Geographical Society, at Goloustnaya, on the west coast, has been closed. A rich collection of fishes, especially of Cottus species, and a great variety of Gammarus species have, however, been secured, and the latter are in the hands of Prof. Sars, of Christiania.

ON Tuesday, July 16, a deputation of members of Parliament and engineering and shipbuilding societies waited upon Lord

Selborne (First Lord of the Admiralty) and Mr. Arnold-Forster (Parliamentary Secretary to the Admiralty), at Whitehall, to urge the necessity of improving the conditions of the service of engineers in the Royal Navy. Lord Selborne promised that the suggestions of the deputation would be carefully considered.

THE French Société d'Encouragement pour l'Industrie nationale announces the following awards of prizes:—Grand gold medal to the Chamber of Commerce of Lyons for the organisation of the commercial mission to China; 2000 francs to M. Horsin-Déon for his work on beetroot sugar; 500 francs to M. R. Fosse for his works on β-dinaphthol, and the same amount to M. Marcel Guichard for his works on molybdenum; 1000 francs to M. Triboudeau for his study of the Pas-de-Calais, and 1000 each to MM. Faure and Thénard for memoirs on the utilisation of waters in agriculture.

A REUTER telegram from St. Petersburg, dated July 11, says:—The St. Petersburg Academy of Sciences to-day received a telegram from the leader of the expedition which is shortly to bring to St. Petersburg the mammoth found in Siberia. The telegram, which is despatched from Yakutsk, reports that the expedition arrived at that place on June 14. It is proceeding by steamer up the river, and will then journey overland to Kolymsk, which is 3000 versts off, and where it expects to arrive in two-and-a-half months. The mammoth found is unique of its kind. Its hair, skin and flesh are entirely preserved, and there are remains of undigested food in its stomach.

AN interesting relic is reported by the *Times* to have been placed in the building of the Academy of Sciences at Tsarskoe-Selo. It is a large geographical globe, 11 ft. in diameter and made of copper. This globe was commenced in the year 1654 and completed ten years later during the reign of Duke Frederick of Holstein. The outside represents the earth, and the interior the celestial spheres of the world. There is a door giving access to the interior of this globe, and in the centre is a round table with space for twelve people to sit. By means of mechanism this great globe can be made to revolve upon its axis. The globe weighs about 3½ tons and was presented to the Academy of Sciences in 1725, but until now it has stood in the Zoological Museum at Tsarskoe-Selo.

THE executive committee of the National Physical Laboratory have made the following appointments:—Superintendent of the engineering department, Dr. T. E. Stanton; assistants in the physics department, Dr. J. A. Harker, Mr. A. Campbell and Dr. H. C. H. Carpenter; junior assistants, Mr. B. F. E. Keeling and Mr. F. E. Smith. It is expected that one or two more junior assistants will be appointed shortly. The alterations to Bushy House and the new buildings for the engineering laboratory are well advanced, and it is hoped to commence work early in October. Of the staff, Dr. Stanton, after serving an apprenticeship with an engineering firm in the Midlands, has had a distinguished career at Manchester and Liverpool, and is now professor of engineering at University College, Bristol. Dr. Harker and Mr. Campbell have both done work of real value in thermometry and electric measurements, while Dr. Carpenter, who will have charge of the chemical researches, after a successful course at Oxford has gained further experience at Leipzig, under Ostwald, and more recently at Owens College. Mr. Keeling obtained a double first in natural science and mechanical science, respectively, at Cambridge, while Mr. Smith was the most distinguished student of his year at South Kensington, and for two years has been one of Prof. Rücker's assistants.

THE programme has been issued of the meeting of the Iron and Steel Institute, to be held in Glasgow on September 3-6 in connection with Section V. of the International Engineering Congress. The remaining eight sections of the Congress will be under the charge of other institutions. The meetings will be held in the University buildings, which are in immediate proximity to the International Exhibition. The president will deliver a short address, and the following are among the subjects of papers:—The nomenclature of metallography; the presence of calcium in high-grade ferro-silicon; the spectra of flames at different periods during the basic Bessemer blow; iron and copper alloys; the correct treatment of steel; the profitable utilisation of power from blast-furnace gas; Brinell's method of determining hardness and other properties of iron and steel; internal strains in iron and their bearing upon fracture; and a mechanical gas producer.

A SATISFACTORY trial of a new airship, devised by M. Santos Dumont, took place at Paris early on Saturday morning. It may be remembered that M. Henry Deutsch has offered a prize of 100,000 francs (4000*l.*) to the inventor of a flying machine which would travel from the heights of Saint Cloud to and round the Eiffel Tower and back again to the starting point in half an hour. M. Santos Dumont did the journey in forty-one minutes on Saturday, that is to say he made a voyage of nearly ten miles at a speed of about fifteen miles an hour, though the return journey was against the wind. He did not win the prize, but his attempt is very encouraging, for he has shown that an airship can be made to travel at a high speed in any direction. His airship consists of a cigar-shaped balloon, six metres in diameter, thirty-four metres long, and having a volume of 550 cubic metres. The gas pressure is kept constant automatically by means of a ventilator driven by the engine and communicating with the balloon by means of a long canvas pipe. Suspended from the balloon is a light framework containing a petroleum motor of 16 horse-power, driving shaft, propeller and rudder, and near one end is a small wickerwork car in which the aëronaut stands and controls the steering-wheel and the apparatus for regulating the motor. M. Deutsch is constructing a similar balloon to that of M. Santos Dumont, but having a volume of 2000 cubic metres and a motor of sixty horse-power. M. Santos Dumont proposes to make another trial trip next Saturday. When going at full speed the propeller makes 200 revolutions per minute.

THE annual report of the Russian Geographical Society for 1900, which has only recently reached us, is, as usual, full of interest. It is especially interesting to notice the growing activity of the young branches of the Society at Vladivostok, Kiakhta, Tomsk and Orenburg—their work being not limited to pure geography, but being mainly directed to the exploration of the geology, botany, zoology and prehistoric anthropology of the respective regions. A new local museum has consequently been opened at Troitskosavsk, near Kiakhta, in addition to those of Minusinsk and Yeniseisk. The chief medal of the Geographical Society, the Constantine medal, was awarded this year to V. Obrucheff, the explorer of the Nan-shan and Mongolia, who has also explored very large portions of Transbaikalia and the Pacific littoral, and whose preliminary reports are always of the deepest interest for both the geologist and the orographer. The Count Lütke medal was awarded to M. E. Zhdanko for his extensive geodetical and hydrographical works in the far North, the Semenoff medal to J. A. Kersnovsky for work in meteorology, and the Prjevalski medal to the Tomsk professor, V. V. Sapozhnikoff, whose explorations of the Altai highlands revealed hundreds of unknown glaciers, as well as widely-spread traces of glaciation, and threw much new light on the geography of the whole region. These researches are now embodied in a work, "The Katuñ and its Sources" (with maps and a summary in French).

THE arrangements made for the meetings of the fifth International Congress of Zoology, to be held in Berlin on August

12-16, were described at the beginning of this year (January 3, p. 236), when the invitation circular was distributed. We are now informed that 114 papers have been proposed by zoologists of various nationalities, so that the Congress promises to be of real scientific importance. The magnificent rooms of the German House of Parliament have been put at the disposal of the Congress, and, with the exception of a few lectures to be delivered in the Chemical Institute of the University, all the meetings will be held in the Reichstag building. The sections of the Congress will be: I. General zoology; II. Vertebrata (biology, classification, distribution); III. Vertebrata (anatomy, histology, embryology); IV. Evertebrata except Arthropods; V. Arthropoda; VI. Economic zoology (fisheries, &c.); VII. Nomenclature. Zoologists who wish to read papers should send abstracts not exceeding fifteen lines of print to the Præsidium of the Congress not later than August 1. The complete papers must be sent in not later than October 1. The Congress will be opened at the Reichstagsbäude on Sunday, August 11, at 8 p.m. The subjects of lectures to be delivered in the course of the meeting are: the malarial problem from a zoological point of view, by Prof. G. B. Grassi; vitalism and mechanism, by Prof. Bütschli; theories of fertilisation, by Prof. Yves Délage; the psychological attributes of ants, by Prof. Forel; mimicry and natural selection, by Prof. E. B. Poulton; fossil remains of man, by Prof. Branco. Letters and applications for tickets should be addressed to the Präsidium des V. Internationalen Zoologen-Congresses, Berlin N. 4, Invalidenstrasse 43.

THE new pathological institute connected with the London Hospital Medical College was opened by Sir Henry Roscoe on July 10. The building has cost 20,000*l.*, the fitting-up will need another 1000*l.* and the carrying on of the department will cost about 1200*l.* a year. The director of the institute is Dr. Bullock. Mr. Sydney Holland, who occupied the chair at the opening ceremony, remarked that in the new laboratories studies of the causes of disease could be made under conditions which made success possible and advance probable. There would be an orderly continuity of observation which had hitherto been impossible and which would be carried on by men who were specially trained in that science and who loved it for its own sake and for its benefit to their fellow men. This was work by which the whole country would benefit, and yet they got no help from the Government. Scotch hospitals and Irish hospitals obtained grants from the Government, but English hospitals got none and were cramped in every direction for funds. Every German town, even small ones, had its pathological laboratories. The County Council had established one at Claybury, but the one they were opening was the first attempt in London to deal so completely with this most important branch of medical knowledge. In opening the building, Sir Henry Roscoe remarked that it was unique among the large hospitals of London. It was the most completely equipped department for dealing with pathology in a manner worthy of the importance of that branch of medical science. For it was now generally acknowledged that pathology was an essential portion of those studies which made up the great science of medicine. It was necessary to have a centre where pathology was studied for its own sake and not for purposes of immediate practical application, still less for mere examinational purposes. The institute would form, he trusted, an introductory stage for entrance to that still higher and more advanced school of research which had its home in he Jenner Institute at Chelsea.

AN unfortunate controversy having arisen on the question of priority in the proof of the mosquito theory of the transference of malarial infection, Major Ronald Ross has published some correspondence on the subject which shows that the claims of some of the Italian observers cannot be substantiated ("Letters from Rome on the New Discoveries in Malaria," 1900). These eight letters were written by Dr. Edmonston Charles, a resident in Rome, to Major Ross, then in India, and date from November 4, 1898, to January 14, 1899; a letter from Dr. Daniels is included, and they are preceded by a critical introduction, and terminate with a postscript and bibliography by Ross. At this period the Italians, notably Grassi, Bignami and Bastianelli, were endeavouring to follow Ross's investigations on the development of the malarial parasites in the mosquito, and Dr. Charles acted as an intermediary, informing Ross of the progress made by the Italians, and similarly communicating to the latter Ross's observations and handing them his specimens. In the first letter, Charles asks for specimens for Marchiafava "of the mosquito in which human malaria develops." Grassi now denies that Ross ever detected this species. It is pointed out how closely the Italians followed and how well informed they were of the details of Ross's work, yet now Grassi states that his labours were independent of Ross. In the third letter, with regard to the cultivation of crescents in the "dappled winged mosquito" by Ross, Charles says, "he (Grassi) seemed perfectly satisfied that your description referred to the *Anopheles claviger*." Grassi now contends that he could not identify the malaria-bearing mosquito from Ross's description. Bignami, Grassi and Bastianelli have frequently stated that Ross's first successful experiments with human malaria were unsound, because the insects employed might have already bitten another animal before having been fed on man. Yet in Ross's publication it is clearly premised that the insects had been bred in bottles from the larvæ. These and other claims are dealt with in this publication.

THE art of producing decorative illuminating effects by the use of electric light is one that has in recent years called forth the application of great engineering skill. Particular attention has been given to this point at the Pan-American exhibition now being held at Buffalo, and those who are fortunate enough to visit this exhibition will be able to admire what is probably the most comprehensive and carefully studied system of illumination that has as yet been carried out. The less fortunate can obtain some idea of the great beauty of some of the effects from the very excellent photographs that have been recently appearing in the *Electrical Review* of New York. Those responsible for the illumination at Buffalo were to a certain extent favoured by circumstances in that they had a cheap supply of electricity available from the neighbouring power station at Niagara. It was thus possible, not only to get current cheaply, but also to control the lighting of the whole exhibition from one centre. Power is transmitted from Niagara, 20 miles distant, at a pressure of 11,000 volts, and after undergoing a transformation down to an intermediate voltage of 1800 is again transformed down to the voltage for supplying the lamps. An additional effect is produced by gradually bringing up the lamps from darkness to full candle power instead of switching on the full light instantaneously. To carry this out the whole of the current used for illuminating the buildings is passed through three large water rheostats, consisting of iron tanks 10 feet long by 3 feet wide and 3 feet deep, into which cast-iron plates, 8 feet long by $\frac{3}{4}$ inch thick, are slowly lowered; when the plate reaches the bottom of the tank it strikes a clip which short circuits the rheostat. The three rheostats are worked simultaneously, the plates being lowered and raised by a small electric motor; 45 seconds is taken to light up the lamps, which are put out in a somewhat longer period of about 75 seconds.

THE director of the Belgian Meteorological Service has recently published a very useful memoir on the direction of the wind at Brussels, compiled from fifty years' observations (1842-1891). The work forms the third part of the series, those referring to barometric pressure and air temperature having already appeared. The wind-directions are grouped in various ways; among the tables we find the relative frequency arranged under sixteen points of the compass, for each month and for each season, during the fifty separate years deduced from the hourly or two-hourly indications of a self-recording anemometer. The plates containing the average monthly and yearly wind-roses show the prevailing directions more clearly than anything else could do. It is seen at a glance that the winds between south-west and west are more frequent than all the other directions combined.

SIGNOR G. ODDO, writing in the *Atti dei Lincei* on the use of oxychloride of phosphorus as a solvent in cryoscopic observations, finds that the cryoscopic constant of this solvent is 69, and that, like water, but within narrower limits, it ionises dilute saline solutions.

THE stability of a given state of motion is a subject on which much has been written and more remains to be written. A paper on certain criteria of instability, by Signor T. Levi-Cività, appears in the *Annali di matematica pura ed applicata*. After discussing the general theory, the author proceeds to consider the problem of three bodies, and shows in particular that periodical solutions approximating to uniform circular motions are unstable, a conclusion contrary to what would naturally be inferred from considerations of celestial mechanics. The same author, writing in the *Atti dei Lincei*, deals with the stationary motions of a rigid body in the case of Kowalevsky.

DR. F. CAUBET, of the University of Bordeaux, has published a lengthy thesis on the liquefaction of gaseous mixtures, dealing in particular with the phenomena of the critical point and of retrograde condensation. In it the author describes an elaborate series of experimental determinations of the isothermal lines, the lines of Gibbs and Konowaloff, and the dew- and boiling-points of three series of mixtures each formed of two of the three gases, methyl chloride, carbonic anhydride and sulphurous anhydride. By tracing the isothermals for different degrees of concentration, both in the homogeneous and in the heterogeneous states, Dr. Caubet hopes to throw experimental light on the theories derived from considerations of the thermodynamic potential.

AN account of the earthquake of April 24, in the neighbourhood of Palombara Sabina, is given by Dr. Luigi Palazzo in the *Atti dei Lincei*, x. 9. The shock was registered at the Central Meteorological Office at about 15h. 20m. 25s. Italian time, and lasted about five to six seconds. The town of Palombara was visited without delay by Prof. Cancani, who found that the damage in the centre of the town was small; but in the village of Stazzano four or five houses were destroyed, others rendered uninhabitable, while considerable damage was done at Cretone, and the author thinks it probable that the epicentre was at a sulphur spring about a kilometre distant from Cretone, and that the origin of the shock was in the strata from which the spring arises, at a comparatively small depth.

THE current number of the *Journal of Hygiene* contains, amongst other articles, an appreciative obituary notice of Prof. Max von Pettenkofer, accompanied by an excellent portrait. Pettenkofer's name is now so invariably associated with investigations in the department of hygiene that his earlier work in pure chemistry runs a risk of being overlooked. As long ago as 1850 he presented to the Bavarian Academy a paper calling attention to some of the main facts which form the basis of the periodic law of the elements, but, like Newlands in this country, his work obtained no recognition at the time, and it was only in 1899 that the German Chemical Society conferred upon him the Liebig medal in tardy recognition of the merit of his researches of nearly half a century before. It was largely due to Pettenkofer that Germany has now chairs of hygiene with magnificent laboratories in all but one of her twenty universities, besides the famous Imperial Institute of Public Health in Berlin.

IN their Report for the past year the council of the Leicester Literary and Philosophical Society announce that they are cooperating with the National Trust for the Preservation of Objects of Historical Interest or Natural Beauty, and that steps are being taken to register and protect such objects in the county as may come within the scope of the Society's aims. The *Transactions* (issued with the Report) contain a lecture on heredity and the question of the inheritance of acquired characters, by Mr. C. J. Bond. Dr. J. G. Adams, professor of pathology at McGill University, sends us a reprint from the *New York Medical Journal* for June of an address on the same subject, in which he proposes to supersede Weismann's and allied theories on heredity and inheritance by one of his own.

AN article on the fauna of the Antarctic ("La Faune du pôle-Sud"), contributed by M. E. G. Racovitza to the *Revue Scientifique* for July 6, appears opportunely. It is based on the results of the recent Belgian expedition and contains a general account of the fauna, with special details of the habits of the penguins, and a few notes on the flora. Since the whole of the Antarctic land (both continent and islands) appears to be invested with an unbroken sheet of inland ice (miscalled *inlandsis*), the author does not hold out hopes of the discovery of any important new types of life in the interior.

TO the January issue of the *Journal* of the Straits branch of the Royal Asiatic Society, Mr. H. N. Ridley, director of the Botanical Gardens at Singapore, communicates an extremely interesting paper on the flora of Mount Ophir. This flora includes three factors, a lowland Malay element, specially modified for existence at a higher elevation, the usual Oriental alpine (or Himalayan) element and—what is most interesting and unexpected—an Australian element. The same journal also contains a list of the butterflies of Mount Penrissen, Sarawak, and one of the reptiles of Borneo, both by Mr. R. Shelford, curator of the Sarawak Museum.

MR. L. M. LAMBE has published a revision of the genera and species of Canadian Palæozoic Corals ("Contributions to Canadian Palæontology," vol. iv. part ii. Geol. Survey Canada, 1901). His work is illustrated by thirteen plates.

IN a brief article on Indiana caves, Dr. O. C. Farrington discusses some peculiar forms of stalactites and stalagmites (*Publications* of the Field Columbian Museum, vol. i. No. 8, geol. series, 1901). The shape of certain vermiform stalactites is attributed, with Merrill, to the fact that drops of water may have been guided to other positions than those dictated by gravity by the directions assumed by spicules of calcite in crystallising. In one huge stalagmite both aragonite and calcite occur, and its minimum age is reckoned at 90,000 years. Lining the walls of a pool in one of the caves are calcite crystals in close association with stalagmites; here the crystals were formed in relatively still water, while the stalactites and stalagmites were formed when the water was moving. The author suggests that in a general way banded structures may be taken as indicating formation from waters in motion, while distinct crystals were formed from waters at rest; and he would apply these principles to the origin of mineral veins, agates, geodes, &c. He proposes the term stagmalites for formations produced by dropping water, and to include stalactites and stalagmites.

THE *Transactions* of the "Antonio Alzate" Society of Mexico contain a paper by MM. Marroquin y Rivera and P. C. Sánchez on the mountain chain of the Ajusco and its subterranean waters. In the northern part of the Vallée de Mexico, which is a closed basin, are two lakes named Chalco and

Xochimilco, containing excellent water, but their level is so low that it could only be made available for supplying the city of Mexico by enormous expenditure for pumping machinery. The basin of these lakes is bounded on the south and east by the mountains of the Ajusco and Sierra Nevada, and on the north by the Santa Catarina; a depression to the north-east connects it with the Vallée de Mexico, of which it forms a part. The lakes are fed by springs draining the underground waters from the volcanic formations of the Sierra Nevada and the Ajusco. The paper, which is an interesting study of the physical geography of the region, gives a preliminary account of attempts to tap these underground waters at a suitable level for gravitational supply to Mexico. The impermeable bed, believed to be andesitic, is being sought for below the basalt lavas and detritus by means of borings.

THE technique of basketry as manufactured by the Amerinds is the subject of a very valuable little paper by Dr. Otis T. Mason in the *American Anthropologist* (n.s., vol. iii. p. 109). Those who have desired to describe baskets and other objects plaited by primitive peoples have long wanted a system upon which to base their studies. This Dr. Mason has supplied, and all who study primitive industries once more have to thank their diligent and systematic American colleague.

THE *Kew Bulletin of Miscellaneous Information* (Appendix iii. 1901) contains the usual annual list of new garden plants recorded during last year in botanical and horticultural publications. The list includes, not only plants brought into cultivation for the first time during 1900, but the most noteworthy of those which have been re-introduced after being lost from cultivation.

A SECOND edition of "Marine Boiler Management and Construction," by Mr. C. E. Stromeyer, has been published by Messrs. Longmans, Green and Co. The book is described in the sub-title as "a treatise on boiler troubles and repairs, corrosion, fuels and heat, on the properties of iron and steel, on boiler mechanics, workshop practices and boiler design"; it was reviewed in these columns when the first edition appeared (vol. xlix. p. 410). About sixty pages of new matter have been added, including a chapter on steam, water and the boiling phenomena. No detailed accounts are given concerning water-tube boilers, because little exact information about the various types is available.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mr. E. Robinson; a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Mr. L. Gough; a Northern Mocking-bird (*Mimus polyglottis*) from North America, a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, a Green Lizard (*Lacerta viridis*), European, presented by Miss Betty Cox; two Chaplain Crows (*Corvus capellanus*) from the Persian Gulf, presented by Mr. B. T. Ffinch; two Olive Weaver-birds (*Hyphantornis capensis*), two Alario Sparrows (*Passer alario*), eight Sulphury Seed-eaters (*Crithagra sulphurata*) from South Africa, presented by Mrs. R. Templeman; a Jackdaw (*Corvus monedula*), British, presented by Mr. L. Peevor; a Green Monkey (*Cercopithecus callitrichus*), a Jardine's Parrot (*Paeocephalus gulielmi*) from West Africa, a Pine Marten (*Mustela martes*), British; three King Snakes (*Coronella getula*), two Mexican Snakes (*Coluber melanoleucus*), a Chained Snake (*Coluber catenifer*), two Corn Snakes (*Coluber guttatus*), two Chicken Snakes (*Coluber obsoletus*), three Testaceous Snakes (*Zamenis flagelliformis*), a Long-nosed Snake (*Heterodon nasica*), an Amphiuma (*Amphiuma means*), three Menopomas (*Cryptobranchus alleghaniensis*), two Menobranchs (*Necturus maculatus*) from North America, deposited; two Barbary Wild Sheep (*Ovis tragelaphus*), a Japanese Deer (*Cervus sika*), a Yak (*Poephagus grunniens*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

WAVE-LENGTH OF GREEN CORONA LINE.—In the *Mem. della Soc. Degli. Spett. Ital.* (vol. xxx. pp. 124–128), Sig. Ascarza describes the results of observations made at Plascencia by the party from the Madrid Observatory during the total eclipse of the sun on May 27, 1900.

The instrumental equipment consisted of a Grubb coelostat with a mirror 20 centimetres diameter, furnishing light for a Steinheil objective of 12 centimetres aperture and 1·80 metres focus. This produced on the slit of the spectroscope an image of the sun about 16 millimetres in diameter.

A Dubosq spectroscope was used, furnished with six prisms and eyepiece micrometer reading to 1 : 300th of a millimetre. On account of the absorption of the prisms, only *three* were used for the final observations.

For the determination, measures were made on the lines 5328·696, 5270, 108 (E), and 5183·792 (b_1), and the resulting measures of the corona line reduced by interpolation formulæ. The spectroscope not being sufficiently powerful to separate the components of E, the mean of the wave-lengths of the two was adopted.

Preparation was made for both radial and tangential measures, but on account of the diffuse character of the line the tangential method was applied. The results were reduced by two interpolation formulæ, Gibbs and Hartmann, slightly varying values being obtained. The wave-lengths found on Rowland's scale were 5298·7 and 5298·818 respectively. The paper concludes with a note stating the difference of 4 tenth-metres between this value and that of 5303 obtained by Lockyer and Campbell from photographs taken during the total solar eclipse in India on January 22, 1898.

DEFORMATION OF THE SUN'S DISC.—In the *Mem. della Soc. Degli. Spett. Ital.* (vol. xxx. pp. 96–110), Sig. A. Ricco describes a long series of observations, both visual and photographic, of the varying deformations of the disc of the sun by the effect of atmospheric refraction, made at the observatories of Palermo and Catania (Etna). Many of the visual observations were made with a small Ramsden telescope having a terrestrial eyepiece, magnifying five times; photographs were also taken with a Merz telescope of 0·115 metre aperture and 1·93 metres focal length, adjusted to the chemical focus, giving an image about 0·0175 metre diameter.

The paper is illustrated by drawings and reproductions from many of the photographs, which are similar in many respects to those obtained by Colton at the Lick Observatory and published about 1895.

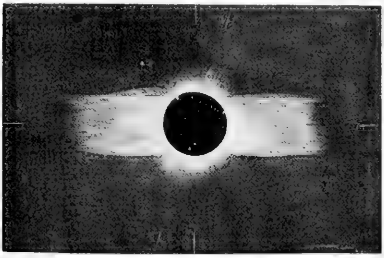
THE MINOR PLANET TERCIDINA.—In the note on p. 265, Prof. Hartmann's observations were misinterpreted. The photographs obtained at the Potsdam Observatory do not confirm the suspected variability suggested by the photograph obtained by Prof. Wolf in November 1899, nor do the later photographs of Prof. Wolf. The apparent variation may possibly be due to instrumental irregularities.

THE TOTAL ECLIPSE OF MAY 18, 1901.

THE following account of the total eclipse of the sun, May 18, is taken from a letter received from Mr. J. Cresswell, who was formerly a student of astronomical physics at the Royal College of Science, and is now engaged at a mining camp near the centre of Borneo (lat. 0° 45′ S., long. 113° E.).

The eclipse commenced about 12.20 in a cloudy sky, but fortunately about 15 minutes before totality the whole sky cleared and revealed a crescent sun. There were only one or two small clouds near the horizon, and the landscape appeared to have a peculiar violet tinge. There was no fall in temperature up to this point, the thermometer having remained stationary at 34°·75 C. Four minutes afterwards the landscape appeared as if seen through smoked glass, the temperature now being 34°·5. After the lapse of another 8 minutes the light was like that when a heavy storm is gathering, and shadows had a peculiar transparency; a number of stars appeared in the heavens distant from the sun. After 2½ minutes more had elapsed, second contact occurred and we were in darkness. The accompanying sketch of the corona was made and a photograph was taken with a small camera. The darkness was such that a small paraffin candle burning 100 metres away appeared quite bright. After about a minute the bright prominence *a* was seen, and it seemed to penetrate slightly into the dark body of the moon; this was seen for quite two minutes. Just before third contact the blood-red chromosphere appeared. At this time the temperature had steadily fallen to 31° C., but the lowest temperature recorded was 30°·25, at 2h. 6m. 30s., making a total fall in temperature of 4°·5 C.

Through a ruby glass the corona was invisible, except an irregular rim about one-eighth of the sun's diameter in width.



No air movements were noticed during the eclipse. Birds were not noticed to go to roost, but it was stated that some fowls did so. There is an insect known to the Dyaks as the "six o'clock insect," which invariably gives utterance to a very loud horn-like cry just before dark (*i.e.* about 6 p.m.), but its call was not heard during the eclipse.

THE AIMS OF THE NATIONAL PHYSICAL LABORATORY.[1]

THE idea of a physical laboratory in which problems bearing at once on science and on industry might be solved is comparatively new. The Physikalisch-Technische Reichsanstalt, founded in Berlin by the joint labours of Werner von Siemens and von Helmholtz during the years 1883–87, was perhaps the first. It is less than ten years since Dr. Lodge, in his address to Section A of the British Association, outlined the scheme of work for such an institution here in England. Nothing came of this; a committee met and discussed plans, but it was felt to be hopeless to approach the Government, and without Government aid there were no funds.

Four years later, however, the late Sir Douglas Galton took the matter up. In his address to the British Association in 1895, and again in a paper read before Section A, he called attention to the work done for Germany by the Reichsanstalt and to the crying need for a similar institution in England.

The result of this presidential pronouncement was the formation of a committee which reported at Liverpool, giving a rough outline of a possible scheme of organisation. A petition to Lord Salisbury followed, and as a consequence a Treasury committee, with Lord Rayleigh in the chair, was appointed to consider the desirability of establishing a National Physical Laboratory. The committee examined more than thirty witnesses and then reported unanimously "that a public institution should be founded for standardising and verifying instruments for testing materials and for the determination of physical constants."

It is natural to turn to the words of those who were instrumental in securing the appointment of this committee, and to the evidence it received, in any endeavour to discuss its aim. As was fitting, Sir Douglas Galton was the first witness to be called. It is a source of sorrow to his many friends that he has not lived to see the Laboratory completed.

And here may I refer to another serious loss which, in the last few days, the Laboratory has sustained. Sir Courtenay Boyle was a member of Lord Rayleigh's committee, and as such was convinced of the need for the Laboratory and of the importance of the work it could do. He took an active part in its organisation, sparing neither time nor trouble; he intended that it should be a great institution, and he had the will and the power to help. The country is the poorer by his sudden death.

Let me now quote some of Sir Douglas Galton's evidence. "Formerly our progress in machinery," he says, "was due to accuracy of measurement, and that was a class of work which could be done, as Whitworth showed, by an educated eye and educated touch. But as we advance in the applications of science to industry we require accuracy to be carried into matters which cannot be so measured. . . . In the more delicate researches which the physical, chemical and electrical student undertakes, he requires a ready means of access to standards to enable him to compare his own work with that of others." Or again, "My view is that if Great Britain is to retain its industrial supremacy we must have accurate standards available to our research students and to our manufacturers. I am certain that if you had them our manufacturers would gradually become very much more qualified for advancing our manufacturing industry than they are now. But it is also certain that you cannot separate some research from a standardising department." Then, after a description of the Reichsanstalt, he continues, "What I would advocate would be an extension of Kew in the direction of the second division of the Reichsanstalt, with such auxiliary research in the establishment itself as may be found necessary." The second division is the one which takes charge of technical and industrial questions. Prof. Lodge, again, gave a very valuable summary of work which ought to be done.

It is now realised, at any rate by the more enlightened of our leaders of industry, that science can help them. This fact, however, has been grasped by too few in England; our rivals in Germany and America know it well, and the first aim of the Laboratory is to bring its truth home to all, to assist in promoting a union which is certainly necessary if England is to retain her supremacy in trade and in manufacture, to make the forces of science available for the nation, to break down by every possible means the barrier between theory and practice, and to point out plainly the plan which must be followed unless we are prepared to see our rivals take our place.

"Germany," an American writer who has recently made a study of the subject has said, "is rapidly moving towards industrial supremacy in Europe. One of the most potent factors in this notable advance is the perfected alliance between science and commerce existing in Germany. Science has come to be regarded there as a commercial factor. If England is losing her supremacy in manufactures and in commerce, as many claim, it is because of English conservatism and the failure to utilise to the fullest extent the lessons taught by science, while Germany, once the country of dreamers and theorists, has now become intensely practical. Science there no longer seeks court and cloister, but is in open alliance with commerce and industry." It is our aim to promote this alliance in England, and for this purpose the National Physical Laboratory has been founded.

It is hardly necessary to quote chapter and verse for the assertion that the close connection between science and industry has had a predominant effect on German trade. If authority is wanted, I would refer to the history of the anilin dye manufacture, or, to take a more recent case, to the artificial indigo industry, in which the success of the Badische Company has recently been so marked. The factory at Ludwigshaven started thirty-five years ago with 30 men; it now employs more than 6000 and has on its staff 148 trained scientific chemists. And now, when it is perhaps too late, the Indian planters are calling in scientific aid and the Indian Government are giving some 3500*l.* a year to investigation.

As Prof. Armstrong, in a recent letter to the *Times*, says, "The truly serious side of the matter, however, is not the prospective loss of the entire indigo industry so much as the fact that an achievement such as that of the Badische Company seems past praying for here." Another instance is to be found in the German exhibit of scientific instruments at the Paris Exhibition, of which a full account appeared in the pages of NATURE.

And now, having stated in general terms the aims of the Laboratory and given some account of the progress in Germany, let me pass to some description of the means which have been placed at our disposal to realise those aims. I then wish, if time permits, to discuss in fuller detail some of the work which it is hoped we may take up immediately.

The Laboratory is to be at Bushy House, Teddington. I will

[1] A discourse delivered at the Royal Institution on Friday, May 24, by Dr. R. T. Glazebrook, F.R.S., Director of the Laboratory.

pass over the events which led to the change of site from the Old Deer Park at Richmond to Bushy. It is sufficient to say that at present Kew Observatory in the Deer Park will remain as the Observatory department of the Laboratory, and that most of the important verification and standardisation work which in the past has been done there will still find its home in the old building.

Bushy House was originally the official residence of the Ranger of Bushy Park. Queen Anne granted it in 1710 to the first Lord Halifax. In 1771 it passed to Lord North, being then probably rebuilt. Upon the death of Lord North's widow in 1797, the Duke of Clarence, afterwards William IV., became Ranger; after his death in 1837 it was granted to his widow, Queen Adelaide, who lived there until 1849. At her death it passed to the Duc de Nemours, son of King Louis Philippe, and he resided there at intervals until 1896.

In spite of this somewhat aristocratic history, it will make an admirable Laboratory. A description of the Laboratory, with illustrations, will be found in NATURE, vol. lxiii. p. 300.

The floor space available is much less than that of the Reichsanstalt. But size alone is not an unmixed advantage; there is much to be said in favour of gradual growth and development, provided the conditions are such as to favour growth. Personally I should prefer to begin in a small way if only I felt sure I was in a position to do the work thoroughly, but there is danger of starvation. Even with all the help we get in freedom from rent and taxes, outside repairs and maintenance, the sum at the disposal of the committee is too small.

Science is not yet regarded as a commercial factor in England. Is there no one who realises the importance of the alliance, who will come forward with more ample funds to start us on our course with a fair prospect of success? One candid friend has recently told us in print that the new institution is on such a microscopic scale that its utility in the present struggle is more than doubtful. Is there no statesman who can grasp the position and see that with, say, double the income the chances of our doing a great work would be increased a hundredfold?

The problems we have to solve are hard enough; give us means to employ the best men and we will answer them, starve us and then quote our failure as showing the uselessness of science applied to industry.

There is some justice in the criticism of one of our technical papers. I have recently been advertising for assistants, and a paper in whose columns the advertisement appears writes, "The scale of pay is certainly not extravagant. It is, however, possible that the duties will be correspondingly light."

Now let me illustrate these aims by a more detailed account of some of the problems of industry which have been solved by the application of science, and then of some others which remain unsolved and which the Laboratory hopes to attack. The story of the Jena Glass Works is most interesting; I will take it first.

An exhibition of scientific apparatus took place in London in 1876. Among the visitors to this was Prof. Abbé, of Jena, and in a report he wrote on the optical apparatus he called attention to the need for progress in the art of glass making if the microscope were to advance, and to the necessity for obtaining glasses having a different relation between dispersion and refractive index than that found in the material at the disposal of opticians. Stokes and Harcourt had already made attempts in this direction, but with no marked success.

In 1881 Abbé and Schott, at Jena, started their work. Their undertaking, they write five years later in the first catalogue of their factory, arose out of a scientific investigation into the connection between the optical properties of solid amorphous fluxes and their chemical constitution. When they began their work some six elements only entered into the composition of glass. By 1888 it had been found possible to combine with these, in quantities up to about 10 per cent., twenty-eight different elements, and the effect of each of these on the refractive index and dispersion had been measured. Thus, for example, the investigators found that by the addition of boron the ratio of the length of the blue end of the spectrum to that of the red was increased; the addition of fluorine potassium or sodium produced the opposite result.

Now in an ordinary achromatic lens of crown and flint, if the total dispersion for the two be the same, then for the flint glass the dispersion of the blue end is greater, that of the red less than for the crown; thus the image is not white, a secondary spectrum is the result.

Abbé showed, as Stokes and Harcourt had shown earlier, that by combining a large proportion of boron with the flint its dispersion was made more nearly the same as that of the crown, while by replacing the silicates in the crown glass by phosphates a still better result was obtained, and by the use of three glasses three lines of the spectrum could be combined; the spectrum outstanding was a tertiary one, and much less marked than that due to the original crown and flint glass. The modern microscope became possible.

The conditions to be satisfied in a photographic lens differ from those required for a microscope. Von Seidel had shown that with the ordinary flint and crown glasses the conditions for achromatism and for flatness of field cannot be simultaneously satisfied. To do this we need a glass of high refractive index and low dispersive power, or *vice versâ*; in ordinary glasses these two properties rise and fall together. By introducing barium into the crown glass a change is produced in this respect. For barium crown the refractive index is greater and the dispersive power less than for soft crown.

With two such glasses, then, the field can be achromatic and flat. The wonderful results obtained by Dallmeyer and Ross in this country, by Zeiss and Steinheil in Germany, are due to the use of these new glasses. They have also been applied with marked success to the manufacture of the object glasses of large telescopes.

But the Jena glasses have other uses besides optical. "About twenty years ago"—the quotation is from the catalogue of the German exhibition—"the manufacture of thermometers had come to a dead stop in Germany, thermometers being then invested with a defect, their liability to periodic changes, which seriously endangered German manufacture. Comprehensive investigations were then carried out by the Normal Aichungs Commission, the Reichanstalt and the Jena Glass Works, and much labour brought the desired reward."

The defect referred to was the temporary depression of the ice point which takes place in all thermometers after heating. Let the ice point of a thermometer be observed; then raise the thermometer to, say, 100°, and again observe the ice point as soon as possible afterwards; it will be depressed below its previous position. In some instruments of Thuringian glass a depression of as much as 0°·65 C. had been noted. For scientific purposes such an instrument is quite untrustworthy. If it be kept at, say, 15° and then immersed in a bath at 30°, its reading will be appreciably different from that which would be given if it were first raised to, say, 50°, allowed to cool quickly just below 30°, and then put into the bath. This was the defect which the investigators set themselves to cure.

Table I. gives some details as to thermometers.

Weber had found in 1883 that glasses which contain a mixture of soda and potash give a very large depression. He made a glass free from soda with a depression of 0°·1. The work was then taken up by the Aichungs Commission, the Reichsanstalt and the Jena factory. Weber's results were confirmed. An old thermometer of Humboldt's, containing 0·86 per cent. of soda and 20 per cent. of potash, had a depression of 0°·06, while a new instrument, in which the percentages were 12·7 per cent. and 10·6 per cent. respectively, had a depression of 0°·65.

An English standard, with 1·5 per cent. of soda and 12·3 per cent. of potash, gave a depression of 0°·15, while a French "verre dur" instrument, in which these proportions were reversed, gave only 0°·08.

It remained to manufacture a glass which should have a low depression and at the same time other satisfactory properties. The now well-known glass 16''' is the result. Its composition is shown in the Table.

The fact that there was an appreciable difference between the scale of the 16''' glass and that of the air thermometer led to further investigations, and another glass, a borosilicate containing 12 per cent. of boron, was the consequence. This glass has a still smaller depression.

Previous to 1888 Germany imported optical glass. At that date nearly all the glass required was of home manufacture. Very shortly afterwards an export trade in raw glass began, which in 1898 was worth 30,000*l.* per annum, while the value of optical instruments, such as telescopes, field-glasses and the like, exported that year was 250,000*l.* Such are the results of the application of science, *i.e.* organised common sense, to a great industry. The National Physical Laboratory aims at doing the like for England.

I have thus noted very briefly some of the ways in which science has become identified with trade in Germany, and have indicated some of the investigations by which the staff of the Reichsanstalt and others have advanced manufactures and commerce.

Let us turn now to the other side, to some of the problems which remain unsolved, to the work which our Laboratory is to do and by doing which it will realise the aims of its founders.

The microscopic examination of metals was begun by Sorby in 1864. Since that date many distinguished experimenters, Andrews, Arnold, Ewing, Martens, Osmond, Roberts-Austen, Stead and others, have added much to our knowledge. I am indebted to Sir W. Roberts-Austen for the slides which I am about to show you to illustrate some of the points arrived at. Prof. Ewing a year ago laid before the Royal Institution the results of the experiments of Mr. Rosenhain and himself.

This microscopic work has revealed to us the fact that steel must be regarded as a crystallised igneous rock. Moreover, it is capable, at temperatures far below its melting point, of altering its structure completely, and its mechanical and magnetic properties are intimately related to its structure. The chemical constitution of the steel may be unaltered, the amounts of carbon, silicon, manganese, &c., in the different forms remain the same, but the structure changes, and with it the properties of the steel.

Sections of the same steel polished and etched after various treatments show striking differences. For instance, if a highly carburised form containing 1·5 per cent. of carbon be cooled down from the liquid state, the temperature being read by the deflection of a galvanometer needle in circuit with a thermopile, the galvanometer shows a slowly falling temperature till we reach 1380° C., when solidification takes place; the changes which now go on take place in solid metal. After a time the temperature again falls until we reach 680°, when there is an evolution of heat; had the steel been free from carbon there would have been evolution of heat at 895° and again at 766°. Now throughout the cooling, molecular changes are going on in the steel. By quenching the steel suddenly at any given temperature we can check the change and examine microscopically the structure of the steel at the temperatu re at which it was checked.

[Slides were shown representing the microscopic structures of steels subjected to different treatment as regards temperature and annealing.]

These slides are sufficient to call attention to the changes which occur in solid iron, changes whose importance is now beginning to be realised. On viewing them it is a natural question to ask how all the other properties of iron related to its structure; can we by special treatment produce a steel more suited to the shipbuilder, the railway engineer or the dynamo maker than any he now possesses?

These marked effects are connected with variations in the condition of the carbon in the iron; can equally or possibly more marked changes be produced by the introduction of some other element? Guillaume's nickel steel, with its small coefficient of expansion, appears to have a future for many purposes; can it or some modification be made still more useful to the engineer?

We owe much to the investigations of the Alloys Research Committee of the Institution of Mechanical Engineers. Their distinguished chairman holds the view that the work of that committee has only begun, and that there is scope for such research for a long time to come at the National Physical Laboratory. The executive committee have accepted this view by naming as one of the first subjects to be investigated the connection between the magnetic quality and the physical, chemical and electrical properties of iron and its alloys, with a view specially to the determination of the conditions for low hysteresis and non-agency properties.

At any rate we may trust that the condition of affairs mentioned by Mr. Hadfield in his evidence before Lord Rayleigh's Commission which led a user of English steel to specify that before the steel could be accepted it must be stamped at the Reichsanstalt, will no longer exist.

The subject of wind pressure, again, is one which has occupied this committee's attention to some extent. The Board of Trade rules require that in bridges and similar structures (1) That a maximum pressure of 56 lbs. per square foot be provided for; (2) that the effective surface on which the wind acts should be assumed as from once to twice the area of the front surface, according to the extent of the openings in the lattice girders; (3) that a factor of safety of 4 for the iron work and of 2 for the whole bridge overturning be assumed. These recommendations were not based on any special experiments. The question had been investigated in part by the late Sir W. Siemens.

During the construction of the Forth Bridge Sir B. Baker conducted a series of observations. The results of the first two years' observations are shown in Table II., taken from a paper read at the British Association in 1884. Three gauges were used.

TABLE II.

Revolving gauge.		Small fixed gauge.		Large fixed gauge.	
Mean pressure.		Easterly.	Westerly.	Easterly.	Westerly.
lb.	lb.	lb.	lb.	lb.	lb.
0 to 5	3·09	3·47	2·92	2·04	1·9
5 to 10	7·58	4·8	7·7	3·54	4·75
10 to 15	12·4	6·27	13·2	4·55	8·26
15 to 20	17·06	7·4	17·9	5·5	12·66
20 to 25	21·0	12·25	22·75	8·6	19
25 to 30	27·0		28·5		18·25
30 to 35	32·5		38·5		21·5
Above	65		41·0		35·25
(One observation only above 32·5).					

In No. 1 the surface on which the wind acted was about $1\frac{1}{2}$ square feet in area; it was swivelled so as always to be at right angles to the wind. In No. 2 the area of surface acted on was of the same size, but it was fixed with its plane north and south. No. 3 was also fixed in the same direction, but it had 200 times the area, its surface being 300 square feet.

In preparing the table the mean of all the readings of the revolving gauge between 0 and 5, 5 and 10, &c., lbs. per square foot have been taken, and the mean of the corresponding readings of the small fixed gauge and the large fixed gauge set opposite, these being arranged for easterly and westerly winds.

Two points are to be noticed: (1) only one reading of more than 32·5 lbs. was registered, and this, it is practically certain, was due to faulty action in the gauge.

Sir B. Baker has kindly shown me some further records with a small gauge.

According to these pressures of more than 50 lbs. have been registered on three occasions since 1886. On two other occasions the pressures, as registered, reached from 40 to 50 lbs. per square foot. But the table, it will be seen, enables us to compare the pressure on a small area with the average pressure on a large area, and it is clear that in all cases the pressure per square foot as given by the large area is much less than that deduced from the simultaneous observations on the small area.

The large gauge became unsafe in 1896 and was removed; but the observations for the previous ten years entirely confirm this result, the importance of which is obvious. The same result may be deduced from the Tower Bridge observations. Power is required to raise the great bascules, and the power needed depends on the direction of the wind. From observations on the power some estimate of the average wind pressure on the surface may be obtained, and this is found to be less than the pressure registered by the small wind gauges. Nor is the result surprising, when the question is looked at as a hydrodynamical problem; the lines of fluid near a small obstacle will differ from those near a large one, and the distribution of pressure over the large area will not be uniform. Sir W. Siemens is said to have found places of negative pressure near such an obstacle. As Sir J. Wolfe Barry has pointed out, if the average of 56 lbs. to the square foot is excessive, then the cost and difficulty of erection of large engineering works is being unnecessarily increased. Here is a problem well worthy of attention, and about which but little is known. The same, too, may be said about the second of the Board of Trade rules. What is the effective surface over which the pressure is exerted on a bridge? On this again our information is but scanty. Sir B. Baker's experiments for the Forth Bridge led him to adopt as his rule, Double the plane surface exposed to the wind and deduct 50 per cent. in the case of tubes. On this point again further experiments are needed.

To turn from engineering to physics. In metrology, as in many other branches of science, difficulties connected with the measurement of temperature are of the first importance.

I was asked some little time since to state, to a very high order of exactness, the relation between the yard and the metre. I could not give the number of figures required. The metre is defined at the freezing point of water, the yard at a temperature of 62° F. When a yard and a metre scale are compared they are usually at about the same temperature; the difficulty of comparison is enormously increased if there be a temperature difference of 30° F. between the two scales. Hence we require to know the temperature coefficients of the two standards. But that of the standard yard is not known; it is doubtful, I believe, if the composition of the alloy of which it is made is known, and in consequence Mr. Chaney has mentioned the determination of coefficients of expansion as one of the investigations which it is desirable that the Laboratory should undertake.

Or, again, take thermometry. The standard scale of temperature is that of the hydrogen thermometer; the scale in practical use in England is the mercury in flint glass scale of the Kew standard thermometers. It is obvious that it is of importance to science that the difference between the scales should be known, and various attempts have been made to compare them. But the results of no two series of observations which have been made agree satisfactorily. The variations arise probably in great measure from the fact that the English glass thermometer, as ordinarily made and used, is incapable of the accuracy now demanded for scientific investigations. The temporary depression of the freezing point already alluded to in discussing the Jena glass is too large; it may amount to three- to four-tenths of a degree when the thermometer is raised 100°. Thus the results of any given comparison depend too much on the immediate past history of the thermometer employed, and it is almost hopeless to construct a table, accurate, say, to ·01, which will give the difference between the Kew standard and the hydrogen scale, and so enable the results of former work in which English thermometers were used to be expressed in standard degrees.

TABLE III.—*Values of Corrections to the English Glass Thermometer Scale to give Temperatures on the Gas Thermometer Scale found by various Observers.*

Temp.	Rowland.	Guillaume.	Wiebe.
°	°	°	°
0	0	0	0
10	− ·03	− ·009	+ ·03
20	− ·05	− ·009	+ ·00
30	− ·06	− ·002	+ ·02
40	− ·07	+ ·007	+ ·09
50	− ·07	+ ·016	+ ·14
60	− ·06	+ ·014	
70	− ·04	+ ·028	
80	− ·02	+ ·026	
90	− ·01	+ ·017	
100	0	0	

This is illustrated by Table III., which gives the differences as found (1) by Rowland; (2) Guillaume; (3) Wiebe between a Kew thermometer and the air thermometer.

It is clearly important to establish in England a mercury scale of temperatures which shall be comparable with the hydrogen scale, and it is desirable to determine as nearly as may be the relation between this and the existing Kew scale.

I am glad to say that in the first endeavour we have secured the valuable cooperation of Mr. Powell, of the Whitefriars Works, and that the first specimens of glass he has submitted to us bid fair to compare well with 16'''.

Another branch of thermometry at which there is much to do is the measurement of high temperature. Prof. Callendar has explained here the principles of the resistance thermometer, due first to Sir W. Siemens. Sir W. C. Roberts-Austen has shown how the thermopile of Le Chatellier may be used for the measurement of high temperatures. There is a great work left for the man who can introduce these or similar instruments to the manufactory and the forge, or who can improve them in such a manner as to render their uses more simple and more sure. Besides, at temperatures much over 1000° C., the glaze on the porcelain tube of the pryometer gives way.

So far we have discussed new work, but there is much to be done in extending a class of work which has gone on quietly and without much show for many years at the Kew Observatory. Thermometers and barometers, wind gauges and other meteorological apparatus, watches and chronometers, and many other instruments are tested there in great numbers, and the value of the work is undoubted. The competition among the best makers for the first place, the best watch of the year, is most striking and affords ample testimony to the importance of the work.

Work of this class we propose to extend. Thus, there is no place where pressure gauges or steam indicators can be tested. It is intended to take up this work, and for this purpose a mercury pressure column is being erected.

Again, there are the ordinary gauges in use in nearly every engineering shop. These, in the first instance, have probably come from Whitworth's, or nowadays, I fear, from Messrs. Pratt and Whitney or Browne and Sharpe, of America. They were probably very accurate when new, but they wear, and it is only in comparatively few large shops that means exist for measuring the error and for determining whether the gauge ought to be rejected or not. Hence arise difficulties of all kinds. Standardisation of work is impossible.

In another direction a wide field is offered in the calibration and standardisation of glass measuring vessels of all kinds, flasks, burettes, pipettes, &c., used by chemists and others. At the request of the Board of Agriculture we have already arranged for the standardisation of the glass vessels used in the Babcock method of measuring the butter fat in milk, and in a few months many of these have passed through our hands. We are now being asked to arrange for testing the apparatus for the Gerber and Leffman-Beam methods, and this we have promised to do when we are settled at Bushy. Telescopes, opera-glasses, sextants, and other optical appliances, are already tested at Kew, but this work can, and will, be extended. Photographic lenses are now examined by eye; a photographic test will be added, and I trust the whole may be made more useful to photographers.

I look to the cooperation of the Optical Society to advise how we may be of service to them in testing spectacles, microscope lenses and the like. The magnetic testing of specimens of iron and steel, again, offers a fertile field for inquiry. If more subjects are needed it is sufficient to turn over the pages of the evidence given before Lord Rayleigh's Commission, or to look to the reports which have been prepared by various bodies of experts for the executive committee.

In electrical matters there are questions relating to the fundamental units on which, in Mr. Trotter's opinion, we may help the officials of the Board of Trade. Standards of capacity are wanted; those belonging to the British Association will be deposited at the Laboratory. Standards of electromagnetic induction are desirable; questions continually arise with regard to new forms of cells other than the standard Clark cell, and in a host of other ways work will be found.

I have gone almost too much into detail. It has been my wish to state in general terms the aims of the Laboratory to make the advance of physical science more readily available for the needs of the nation, and then to illustrate the way in which it is intended to attain those aims. I trust I may have shown that the National Physical Laboratory is an institution which may deservedly claim the cordial support of all who are interested in real progress.

ON THE SEPARATION OF THE LEAST VOLATILE GASES OF ATMOSPHERIC AIR, AND THEIR SPECTRA.[1]

THE separation of these gases from each other was effected by collecting them in a bulb in the solid state and allowing the solid gradually to evaporate at as low a temperature as possible, while the vapour was continually pumped away with a mercurial pump. Between the bulb containing the solidified gases and the pump a sparking tube was interposed, where the spectrum emitted by the vapour under the influence of an electric discharge was from time to time observed.

The success of the operation of separating the gases which boil at different temperatures depends on keeping the temperature of the solid mass as low as possible, as will be seen from the following consideration :—

The pressure, p, of a gas G, above the same material in the liquid state, at temperature T, is given approximately by the formula

$$\log p = A - \frac{B}{T},$$

where A and B are constants for the same material. For some other gas G′ the formula will be

$$\log p_1 = A_1 - \frac{B_1}{T},$$

and

$$\log \frac{p}{p_1} = A - A_1 + \frac{B_1 - B}{T}.$$

Now for argon, krypton and xenon, respectively, the values of A are 6·782, 6·972 and 6·963, and those of B are 339, 496·3 and 669·2; and for these and many other substances $A - A_1$ is always a small quantity, while $\frac{B_1 - B}{T}$ is considerable and increases as T diminishes. Hence the ratio of p to p_1 increases rapidly as T diminishes, and by evaporating the gases always from the solid state and keeping the solid at as low a temperature as possible, the gas first coming off consists in by far the greatest part of that which has the lowest boiling point, and is succeeded, with comparative abruptness, by the gas which has the next higher boiling point. So abrupt indeed is the succession that the nitrogen is almost completely removed before the argon makes its appearance, and the necessity for removing the nitrogen by sparking with oxygen almost wholly avoided. The change from one gas to another is easily detected by examining the spectrum in the sparking tube, and the reservoirs into which the gases are pumped can be changed when the spectrum changes and the fractions separately stored.

The general sequence of spectra, omitting those of nitrogen, hydrogen and compounds of carbon, which were never entirely removed by the process of distillation alone, was as follows: The spectrum of argon was first noticed in succession to nitrogen, and then as the distillation proceeded the brightest rays, green and yellow, of krypton appeared, and then the intensity of the argon spectrum waned, and it gave way to that of krypton until, as predicted by Runge, when a Leyden jar was in the circuit, the capillary part of the sparking tube had a magnificent blue colour, while the wide ends were bright pale yellow. Without a jar the tube was nearly white in the capillary part, and yellow about the poles. As the distillation proceeded, the temperature of the vessel containing the solid mixture being allowed to rise slowly, the brightest of the xenon rays began to appear, namely, the green rays about λ 5420, 5292 and 4922, and then the krypton rays soon died out and were superseded by the xenon rays. At this stage the capillary part of the sparking tube is, with a jar in circuit, a brilliant green, and is still green, though less brilliant, without the jar. The xenon formed the final fraction distilled.

The authors give a long list of the approximate wave-lengths of rays they have observed to be emitted by xenon and krypton under the influence of electric discharge.

The variation of the spectra of both xenon and krypton with variation in the character of the electric discharge is very striking, and has already been the subject of remark, in the case of krypton, by Runge, who has compared krypton with argon in its sensitiveness to changes in the electric discharge. Runge distinguishes krypton rays which are visible without a jar and those which are only visible with a jar discharge. The difference in the intensity of certain rays, according as the discharge is continuous or oscillatory, is no doubt very marked, but, with rare exceptions, the authors have found that the rays which are intensified by the oscillatory discharge can be seen with a continuous discharge when the slit of the spectroscope is wide. Runge used a grating, whereas they have, for the sake of more light, used a prism spectroscope throughout, and were therefore able to observe many more rays than he.

There is one very remarkable change in the xenon spectrum produced by the introduction of a jar into the circuit. Without the jar xenon gives two bright green rays at about λ 4917 and λ 4924, but on putting a jar into the circuit they are replaced by a single still stronger ray at about λ 4922. In no other case have the authors noticed a change so striking as this on merely changing the character of the discharge. It is noteworthy that the ray λ 4922 is close to a well-known helium ray, but other helium rays were not seen in the same spectrum. Changes of the spectrum by the introduction of a jar into the circuit are, however, the rule rather than the exception, and there are changes in the spectrum of krypton which seem to depend on other circumstances. Of many tubes filled with krypton in the manner above indicated, some give with no jar the green ray λ 5571, the yellow ray λ 5871 and the red ray λ 7600 very bright, while other rays are very few, and those few barely visible. Putting a jar into the circuit makes very little difference; the three rays above mentioned remain much the brightest, nearly, though not quite, so bright as before, and the blue rays, so conspicuous in other tubes, though strengthened by the use of the jar, are still very weak. In other tubes the extreme red ray is invisible, the rays at λ 5571 and 5871 absolutely, as well as relatively, much feebler, while the strong blue rays are bright, even brighter than the green and yellow rays above named. In one tube the blue rays could be seen, though not the others. This looks very much as if two different gases were involved, but the authors have not been able to assure themselves of that. The case seems nearly parallel with that of hydrogen. There are some hydrogen tubes which show the second spectrum of hydrogen very bright, and others which show only the first spectrum; the second spectrum is enfeebled or extinguished by introducing a jar into the circuit, while the first spectrum is strengthened; and the conditions which determine the appearance of the ultra-violet series of hydrogen rays have not yet been satisfactorily made out.

It is to be noted that putting the jar out of circuit does not in general immediately reduce the brightness of the rays which are strengthened by the jar discharge. Their intensity fades gradually, and is generally revived, more or less, by reversing the direction of the current, but this revival gets less marked at each reversal until the intensity reaches its minimum. The rays strengthened by the jar discharge also sometimes appear bright, without a jar, on first passing the spark when the electrodes are cold, and fade when the electrodes get hot, reappearing when the tube has cooled again. Moreover, if the discharge be continued without a jar, the resistance in the krypton tubes increases rather rapidly, the tube becomes much less luminous and finally refuses to pass the spark. With an oscillatory discharge the passage of the spark and the brightness of the rays are much more persistent. This seems to point to some action at the electrodes which is more marked in the case of krypton than in that of xenon.

The xenon spectrum is characterised by a group of four conspicuous orange rays of about equal intensities, a group of very bright green rays of which two are especially conspicuous, and several very bright blue rays. The list of xenon rays published by Erdmann does not present any close agreement with that of the authors except as to the strongest green lines. The number of xenon rays observed is very considerable, and some of them lie very near to rays of the second spectrum of hydrogen, but inasmuch as these rays are more conspicuous with a jar in circuit than without, which is not the character of the second spectrum of hydrogen, and as, moreover, many of the brightest of the hydrogen rays are absent from the spectrum of the tubes, the authors conclude that these rays are not due to hydrogen.

Certain rays, tabulated separately, have been as yet observed in only one xenon tube; they include a very strong ultra-violet ray of unknown origin, and due either to some substance other than xenon or to some condition of the tube which has not been repeated in the other tubes.

[1] Abridged from a paper by Prof. G. D. Liveing, F.R.S., and Prof. J. Dewar, F.R.S., read before the Royal Society on June 20.

The authors' krypton rays agree tolerably closely with Runge's list, but outnumber his very considerably, as might be expected when prisms were used instead of a grating. The authors think that the krypton used by Runge must have contained some xenon, and that the rays for which he gives the wave-lengths 5419·38, 5292·37 and 4844·58 were really due to xenon, as they are three of the strongest rays emitted by their xenon tubes, and are weak in, and in some cases absent from, the spectra of their krypton tubes.

Appended to the paper are tables showing wave-lengths of xenon and krypton lines to four figures.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE University of St. Andrews has received information that a legacy of 4000*l.* has been left to it by the late Miss Malcolm for the establishment of medical bursaries and scholarships.

ACTING on the suggestion made by Mr. Chamberlain, the general purposes committee of the Birmingham City Council has resolved to recommend the Council to make a grant to the Birmingham University of the proceeds of a halfpenny rate. This will provide an annual sum of 5000*l.*

THE Agent General for New South Wales intimates that applications are invited from gentlemen qualified to fill the chair of pathology in the University of Sydney. Particulars may be obtained from the Agent General for New South Wales, 9, Victoria Street, London, S.W.

THE Technical Education Board of the London County Council has directed the higher education subcommittee to inquire and report (*a*) as to the need and present provision for special training of an advanced kind in connection with the application of science (especially chemistry and electricity) to industry; (*b*) as to what, if any, developments are needed to secure efficient training in these subjects for senior county scholars and other advanced students who desire to qualify themselves to take leading positions in scientific industries. The Board has arranged to make a grant of 10,000*l.* a year to the University of London, and is thus directly interested in the development of advanced scientific instruction in London.

SCIENTIFIC SERIAL.

American Journal of Mathematics, vol. xxiii. No. 3.—Geometry on the cubic scroll of the second kind, by F. C. Ferry, is the conclusion (34 pp.) of a paper commenced in the last number.—Congruent reductions of bilinear forms, by T. J. I'A. Bromwich, contains an account and a slight extension of a method due to Kronecker (*Gesamm. Werke*, Bd. i. p. 349). This method was employed in the first place for the reduction of two quadratic forms. In the present paper it is applied to four cases of reductions, viz. (1) two symmetric forms (the same as Kronecker's case); (2) a symmetric and an alternate form; (3) two alternate forms; and (4) two Hermite's forms. In cases (1)–(3) the substitutions are congruent, while in (4) they are conjugate imaginaries. Mr. Bromwich gives a list of the principal papers which deal with the problems he has considered in his article. On the imprimitive substitution groups of degree fifteen and the primitive substitution groups of degree eighteen, by E. Norton Martin, was presented, in abstract and in a slightly different form, at the summer meeting of the American Mathematical Society in 1899. Herein he has added two new groups to his original list, viz. the groups with five systems of imprimitivity simply isomorphic to the alternating and symmetric groups of degree five, and he mentions that Dr. Kuhn reported at the February (1900) meeting of the Society that he had carried the investigation further by adding twenty-eight to the seventy groups found by Mr. Martin. The list even now does not claim to be absolutely complete, since omissions are always possible. A somewhat long list of recent papers on the subject is appended to the article.—Removal of any two terms from a binary quantic by linear transformations, by Bessie G. Morrison, discusses these linear transformations and gives applications to the non-singular cubic, quartic, quintic and sextic.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, June 19.—Mr. J. J. H. Teall, V.P.R.S., president, in the chair.—On the use of a geological datum, by Mr. Beeby Thompson. A proper interpretation of geological phenomena frequently requires that allowance shall be made for differential earth-movements that have taken place since the period under consideration. Present differences of level in rocks of the same age may be due to actual differences in depth of the sea-floor on which they were deposited; but they may also be the result of subsequent differential earth-movements. The rock selected as a datum should combine as far as possible the following characteristics:—It should be thin, of considerable horizontal extension, having similarity in physical characters and palæontological contents over a large area, and situated as near as possible, in vertical sequence, to the reference-deposit. In Northamptonshire three formations meet these requirements—the Rhætic Beds, the Marlstone Rock-bed and the Cornbrash. The author applies the Marlstone Rock-bed as a datum to the study of the five chief deep explorations in Northamptonshire, with the following results:—While the old land-surface (below the Trias) now varies in height by more than 250 feet, the variation in thickness of the rocks between it and the Middle Lias only reaches 56½ feet; and although the old land-surface is actually lowest where the Rhætic rocks have not been detected, when compared with the position of the Marlstone it is found to be the highest. The further application of the same method enables the author to recognise Rhætic rocks at Northampton, to correct the record of the Kingsthorpe shaft, and to explain the presence of Triassic saline water in the Marlstone. A revised section of the Kingsthorpe shaft is given. Another point proved is that a general levelling-up process was going on just before the beginning of the Lower Liassic Period, and another at the close of the Middle Liassic Period.—On intrusive, tuff-like, igneous rocks and breccias in Ireland, by Messrs. James R. Kilroe and Alexander McHenry.—Many fragmental igneous rocks, although resembling tuffs, cannot be regarded as ejectamenta on account of their character and mode of occurrence in the field. A series of sections is exhibited to illustrate how tuff-like masses invade black slate of Llandeilo age in the South-east of Ireland, generally adhering to the direction of bedding, but frequently cutting across it and detaching numerous pieces from the slate, which are more abundant near the margins of the intrusion than elsewhere.

PARIS.

Academy of Sciences, July 8.—M. Fouqué in the chair.—On new derivatives of benzylcamphor and benzylidenecamphor, by MM. A. Haller and J. Minguin. In continuation of previous researches it is now shown that the unsaturated acid, $C_6H_5-CH=CH\cdot C_8H_{14}\cdot CO_2H$, obtained by the action of hydrobromic acid on benzylidenecamphor, or by treating bromobenzylcamphor with alcoholic potash or ammonia, combines with a molecule of hydrogen bromide to form phenylbromohomocampholic acid, which, when warmed with hydrobromic acid in acetic acid solution, loses bromine and yields the corresponding hydroxy-acid. The action of bromine on dextrobenzylcamphor results in the formation of two stereoisomeric bromobenzylcamphors which yield benzylidenecamphor on treatment with alcoholic potash. Further bromination of benzylcamphor gives rise to unstable dibromo-derivatives which are converted by the action of potash into ortho- and para-bromobenzylidenecamphors; the para-compound forms bromophenylhydroxyhomocampholic acid on treatment with hydrobromic acid at 100°.—Osmotic pressure and its *rôle* as a protection from cold in the living cell, by M. D'Arsonval. At the low temperature of liquid air animal and vegetable tissues in general become extremely hard and friable, whereas the vitality of yeast and various pathogenic micro-organisms is not impaired even by several weeks' exposure to cold. In explanation of this fact it is suggested that the solidification of such minute cells is prevented by the enormous osmotic pressure exerted therein, and it is shown that in the case of yeast the osmotic pressure may be reduced by the action of hypertonic solutions of certain salts to such an extent as to destroy the power of resisting the influence of cold.—New nebulæ discovered at the Paris Observatory, by M. G. Bigourdan.—Observations of Hall's comet 1901(*a*) at the Rio de Janeiro Observatory, by M. H. Morize.—Solar observations at the Lyon Observatory during the first quarter of 1901, by M. J. Guillaume.—On the conjugate nets of orthogonal and isothermal curves, by M. Demartres.—On the use in series of disjunctive voltameters, by M. Ch. Pollak. A note on a previous communication by the author.—On manganic phosphates, by M. V. Auger. The phosphate obtained by heating manganese nitrate with phosphoric acid at 210° and extracting the fused mass with water has the composition $MnP_6O_{21}+14H_2O$, and is evidently a pyrophosphate; it is dissolved by phosphoric acid, forming a violet solution which soon becomes opalescent and deposits the normal phosphate, $MnPO_4+H_2O$. Manganese metaphosphate, MnP_3O_9, is obtained by heating phosphorus pentoxide with hydrated manganese dioxide.—Action of acid chlorides on methanal, by M. Louis Henry. The author confirms Descudé's recent observation that the presence of zinc chloride facilitates the action of acid chlorides on aldehydes. Benzoyl chloride alone has no action on methanal (trioxymethylene), but in the presence of zinc chloride a rapid reaction takes place with the form of a substance, crystallising in needles, which appears to be chloromethyl benzoate.—Action of vegetable alkaloids on some indicators, by M. A. Astruc. The behaviour of a number of alkaloids towards the indicators helianthin, rosolic acid and phenolphthalein was examined. In order to avoid the dissociating influence of water, ethyl alcohol, amyl alcohol and benzene were employed as solvents. The results obtained depend on the solvent used in each case, as well as on the nature of the alkaloid.—On dinaphthoxanthene, by M. R. Fosse. The action of bromine on dinaphthoxanthene leads to the formation of bromodinaphthoxanthene, a red, crystalline substance melting at 218–220°, which is remarkable in that when warmed with alcohol it undergoes a reaction similar to that exhibited by diazo-derivatives, hydrogen bromide, aldehyde and dinaphthoxanthene being produced. Bisdinaphthoxanthenamine, obtained by the action of alcoholic ammonia on the above-described bromine derivative, is a crystalline compound melting at 230°. Chlorodinaphthoxanthene crystallises in red needles melting at 150°.—Study of the product of the nitration of acetoacetic ether, by MM. L. Bouveault and A. Bongert. The compound previously described as produced by the nitration of acetoacetic ether is shown to be isomeric with, but quite different in its reactions from, the substance which Scholl obtained by the action of silver nitrate on ethyl bromacetate.—On a method of synthesis of acetylenic aldehydes, by MM. Ch. Moureu and R. Delange. The condensation of the ethers of formic acid with the sodium derivatives of true acetylenic hydrocarbons, $R-C\equiv CH$, leads to the formation of acetylenic aldehydes, $R-C\equiv C-CHO$, whilst the ethers of higher acids give rise to acetylenic ketones.—Attempts to render vegetables immune against cryptogamic diseases, by M. J. Beauverie. Seeds and cuttings grown in soil in which the fungus *Botrytis cinerea* had been previously allowed to develop were found to produce plants capable of resisting the action of the fungus.—On the *rôle* of leucocytes in elimination, by M. Henry Stassano.—Glucoproteins as new culture media, of definite chemical composition, for the study of microbes, by M. Charles Lepierre. Nearly all microbes, whether pathogenic or not, grow perfectly in liquids in which the nitrogen is furnished exclusively by glucoproteins.—The structure and function of the nervous system of an acephaloid, by MM. N. Vaschide and C. Vurpas.—Acoustic conductivity and audition, by M. Pierre Bonnier.—On the intermittent spring at Vesse, near Vichy, by M. F. Parmentier. The action of this spring lasts for a period of an hour and takes place three times in 25–27 hours. The water is thrown to a height of 7–8 metres and is accompanied by a copious evolution of carbon dioxide; it has a temperature of 31°, and yields a solid residue of 5·354 grams per litre consisting chiefly of sodium carbonate.

New South Wales.

Royal Society, May 1.—Prof. Liversidge, president, in the chair.—Mr. H. C. Russell, C.M.G., F.R.S., was elected president for the current year.—Prof. Liversidge delivered an address, in the course of which he referred to the Intercolonial Catalogue of Scientific Literature. This work, he said, would annually fill seventeen volumes, and would contain from 160,000 to 200,000 entries yearly, and would prove an inestimable boon, as it would relieve scientific people from much of the trouble now attendant upon hunting up references to scientific subjects. He trusted that some effort would be made to collect and forward material from Australia for inclusion in this catalogue. He was also strongly in favour of a federation of the leading scientific societies in Australia and the establishment of a national Australian academy, and suggested that a site for such an academy, museums, art galleries, and a Federal University and other scientific and educational societies might be reserved in the capital of the Commonwealth. The organisation proposed would somewhat resemble the Continental academies so far as its scope was concerned, but under rules more like those of the Royal Society of London. If the proposal were carried out it would be of great benefit to Australia, not only in its general usefulness, but in the stimulus it would give to the younger scientific men, since election to it would depend upon fitness and merit. It would be very gratifying to all who were interested in the matter if, with the new century and the inauguration of the Commonwealth, there was increased attention paid to the question of instruction in science in the schools and better provision made in this direction, for it would be of great usefulness in training the power of observation of the children and teaching them to think about what they saw and heard. Some of the teaching now done at the University should be given in the schools, and the student would then gain valuable time at the University for things he could not do at school. He did not advocate the teaching of technical or applied sciences in ordinary schools. It was to be regretted that the Sydney University was probably the only modern University that excluded science from its entrance examinations. Prof. Liversidge also made some observations in connection with the advantages of a metric system of weights and measures and a decimal system of coinage. He strongly recommended that its teaching should be compulsory in all the schools of the State. The chief defect of our present system of weights and measures was that there was no simple connection between measures of length, weight and capacity. Investigation showed that in countries where the change to the metric system had been made, no great difficulty was experienced, and an increase of trade had resulted. He strongly urged that increased attention should be paid to commercial education and suggested that, not only should it include a certain amount of instruction in science, but that the standard for the higher branches should be as high as for any of the learned professions, also that part of the course should be given at the University.

ANOTHER BOOK ON BRITISH BIRDS.

A Handbook of British Birds. By J. E. Harting. New and Revised Edition. Pp. xxxi + 520; 35 plates. (London: John C. Nimmo, 1901.) Price 2*l.* 2*s.* net.

IT is now some years since the first edition of this book appeared. The present volume, Mr. Harting points out, is nearly treble the size of the original; and, we might truthfully add, is proportionately as interesting.

The author claims for it that,

"as an attempt to show, in one volume, the precise status of every so-called British bird, distinguishing the rare and accidental visitants from the residents and annual migrants, it conveys information of a kind which is not to be found in any other work on British birds."

Be that as it may, the present volume will prove a valuable addition to the library of every working ornithologist. More especially, perhaps, this book will appeal to the outdoor naturalist and to the "collector." But the "cabinet" naturalist will feel himself scarcely less in need of this work, for scattered throughout its scholarly pages will be found innumerable instances of Mr. Harting's intimate knowledge of his subject, both in the fields of bionomics and of literature.

It is obvious that, in a book of this kind, some sort of systematic arrangement must be followed, and Mr. Harting has been confronted with the difficult task of deciding which of the numerous systems of classification that have from time to time been proposed should be adopted in the present volume. His choice has fallen upon the one more or less in favour during the early part of the nineteenth century. A great feature of this system is the prominence given to the accipitrine birds. Mr. Harting justifies his choice in the following words:—

"The most striking character which distinguishes birds from all other vertebrates (save the *Chiroptera*) is the power of flight, and since that peculiarity is most highly developed in the falcons, which are able to overtake and capture the fastest birds upon the wing, not even excepting swallows and swifts, it seems not unreasonable on this account, if for no other, to place the raptorial birds as the highest type of the class *Aves* at the head of any scheme of classification."

Mr. Harting's contention most certainly demands our serious consideration. Nevertheless, to many the revival of this claim to preeminence for the Raptores will seem reactionary, especially to those who, after mature deliberation and ripe experience, are convinced that the headship of the class Aves must be vested in the Passerine forms, the Corvidæ standing as the type.

Strangely enough, one of the strongest supporters of the last-mentioned view, Prof. Newton, is retained, so to speak, by Mr. Harting for the other side. Justification for this is made out on the ground that Prof. Newton followed this precedent when editing the fourth edition of Yarrel's "British Birds" in 1871. But Mr. Harting has overlooked the fact that since that date the editor of this famous book has changed his views; so that in 1884 we find him, as we have just indicated, a doughty champion for "the new learning." The thirteen years that elapsed between the publication of the fourth edition of Yarrell and the masterly article in the "Encyclopædia Britannica" were memorable years in the annals of ornithology—memorable because of the brilliant work of Parker, Garrod, Gadow and Forbes; and no student of ornithology, least of all Prof. Newton, watching the development of their researches could fail to be impressed with the facts they brought to light, and, being impressed, could resist the conclusions to which these appeared to lead.

But seventeen years have elapsed since the "Encyclopædia" article was written, and in these days of prolific publication we are apt to lose sight even of the many gems buried in these ponderous tomes. Happily for us, the substance of Prof. Newton's article, "Ornithology," was incorporated in the introduction to his "Dictionary of Birds"—a book which has been aptly described as marking "an epoch in ornithology"—wherein it was probably read by many for the first time. Since this is the more accessible of the two, we will quote what Prof. Newton has to say, therefrom. In his introduction to this work, in dealing with the Passeres, he writes, "Thus we reach the true *Oscines*, the last and highest group of birds." Further on he quotes, in the strongest terms of approval, Prof. Parker's dictum, that

"In all respects, physiological, morphological and ornithological, the crow may be placed at the head, not only of its own great series (birds of the *Crow-form*), but also as the unchallenged chief of the whole 'Carinatæ.'"

And finally, towards the conclusion of the introduction, he writes:—

"It is therefore confidently that the present writer asserts . . . that at the head of the class *Aves* must stand the family *Corvidae*, of which family no one will dispute the superiority of the genus *Corvus*, nor in that genus the preeminence of *Corvus corax*—the widely ranging raven of the northern hemisphere."

Whether the crows and the forms associated therewith will be allowed to retain this preeminence—which is to-day generally recognised—time will show. This darkly suggested insecurity of tenure will come probably as a relief to Mr. Harting. He may further take heart of grace in that this indication of a "rift within the lute" has come from a no less qualified authority than Mr. Beddard, who suggests ("Classification of Birds," 1898) that the Passeres and their allies should, perhaps, be rather regarded as primitive, archaic types. "More especially," he writes, in the opening words of the discussion on this subject, "does it appear to me that ornithologists are in error concerning the position of the picarian and passerine birds," and he proceeds to adduce a number of reasons which tend to support this view—reasons which are weighty, and which demand a very careful examination from every aspiring taxonomist.

It will be perceived from the foregoing that the relative positions of the different groups of birds, one to another, are yet by no means clearly defined; therefore, until systematic ornithology assumes a more definite shape, Mr. Harting may fairly claim the right to choose for his book that arrangement which most nearly meets his own views.

In dealing with the systematic position of the swifts and swallows, Mr. Harting will again find himself in opposition to the views held at the present day, at least in this country. Mr. Harting will have it, as some have done before him, that the swifts and swallows are near akin, and brings forward in support of this contention the views expressed by such undoubted authorities as the late W. K. Parker and Mr. F. A. Lucas. But on the other side we have a still greater weight of authority, greater if only in point of numbers, no less than seven ornithologists, whose names are as household words among us, having emphatically committed themselves to the conviction that the swifts are near allies of the humming-birds. These illustrious seven are Beddard, Furbringer, Gadow, Garrod, Newton, Sharpe and Stejneger. About the finality of their decision there can be little doubt.

Other points in the scheme of classification adopted by Mr. Harting would furnish material for comment did space permit, but these are of comparatively minor importance.

In the matter of nomenclature, Mr. Harting will be accused of unorthodoxy; but in much of what he has done in this matter, and in his defence thereof, he has our sympathy.

Orthography and etymology are conspicuous features of this book, and many of Mr. Harting's observations under these heads are extremely interesting. His scholarly handling of these difficult matters will impress every reader of this work. An immense amount of labour must have been spent in digging in this, to most of us, very uninviting field. But the results undoubtedly are well worth the trouble which has been expended.

The field-notes, as might have been expected from Mr. Harting, are exceedingly interesting. We cannot help thinking that in places these could with advantage have been enlarged upon. The author is one of the favoured few who has watched the bittern in the act of "booming." This remarkable noise is, we now know, produced whilst the beak is pointed vertically upwards, an attitude commonly assumed by this bird. Till recently it was generally held that the "booming" of the bittern was made whilst the beak was thrust down either into the mud or water.

The "drumming" or "bleating" of the snipe naturally calls forth some comment from the author. Opinions differ still as to the mechanism by which this is produced. The author is confident that it derives its origin from the vibration of the primaries. Meeves, it will be remembered, contended that it owed its origin to the vibration of the outer tail feathers, which have peculiarly thickened shafts. Still later observers have tried to show that it is due to the operation of both wings and tail, a violent current of air being driven through the tail feathers by the rapid vibration of the wings.

The introduction of coloured plates constitutes a new feature in this handbook.

"They have been executed in response to a repeated demand for a book on British birds with accurately coloured plates *in one volume*."

This, it is contended, it has been possible to do by figuring the head, and sometimes the foot, only. But this demand was surely for a book giving more or less lengthy diagnostic characters, *supplemented* by coloured plates. Mr. Harting's book does exactly the reverse, for his diagnoses, which are rare, are supplementary to the plates. No one would, of course, object to this if the plates completely fulfilled their purpose. This they fail to do, inasmuch as several undoubted British birds are not figured at all. Even if the missing heads were added, the book would still be lacking, for more immature stages are necessary, and some heads must be re-drawn, being quite inaccurate. These latter, however, are very few in number.

There are thirty-five plates in all, stated in the title-page to be "from the original drawings by the late Prof. Schlegel." Only a few of these, however, are by Schlegel, the majority having been drawn by Keulemans many years ago, and some are copied from Wolf. Their arrangement must have been entrusted to a foolish person, for a more stupid, exasperating distribution would have been impossible. Instead of being placed at the end of the book, they are distributed between every ten pages of so. Thus the plate illustrating the buntings faces the text dealing with the sand grouse and capercallie, that containing the finches is intercalated between the text devoted to the pheasant, the small wading birds faces the description of the wild-duck, and so on!

But these are minor blemishes in a work of considerable value, blemishes easily remedied in a second edition which is almost sure to be demanded. The binding, printing and paper leave nothing to be desired, and the book, judged as a whole, should take high rank in ornithological literature. W. P. P.

PRACTICAL PHYSIOLOGY.

An Introduction to Physiology. By William Townsend Porter, M.D., Associate Professor of Physiology in the Harvard Medical School. Pp. xvi + 314. (Cambridge, Mass.: The University Press, 1901.)

THIS new text-book of practical physiology is interesting from two distinct points of view. It is the first important work on the subject which has appeared by an American author, and the faculty for the invention of simple yet efficient mechanical devices which is characteristic of Americans is here reflected in clearly written descriptions of inexpensive apparatus which will, in large part, be novel to the British physiologist, who has, unfortunately, grown up to believe that adequate instruction cannot be given in physiology without expensive and elaborate apparatus and laboratory fittings. But the book has other importance, in that it is an indication of the extent and nature of the teaching that can be given to the medical student under the new system of dealing with the purely scientific subjects of the medical curriculum which has recently been inaugurated at the Harvard Medical School.

The present is a most opportune time to consider any new schemes which have appeared in other lands for the teaching of these "preliminary and intermediate medical studies," as the new London University styles them, when there is so much vexation and anxiety of heart as to how concentration of teaching and saving of labour may be effected under some general scheme which will give the reconstituted University of London a medical faculty in living reality, and not merely one which exists as a coherent body only in a printed list.

If one may judge by the extent of Prof. Porter's text-book, the Harvard student is taught a wider course of practical physiology than is attempted to be taught at any of our London medical schools, and, further, if he be taught the subject in the carefully inductive manner outlined by the author in his preface, he also obtains much more true scientific training in addition to this more extensive course. The latter point is the more important of the two, for, as Prof. Porter truly puts it in his preface, "the student should be trained rather than informed," for "the trained observer can, and must, be trusted to inform himself."

This wider course is covered in a period of four months, while in this country the student of medicine spends two years over physiology. Things do go proverbially quick in America, but this is not the reason for the disparity in time; the explanation is that the Harvard man spends *all* his hours of study during those four months upon physiology, whereas in this country the medical student's time is spent in attempting to make an intimate mixture of physiology, anatomy, organic chemistry and therapeutics. At the end of the two years the result is that the British student has wasted much time in hopping about from one branch of the tree of knowledge to another, and has not spent a sufficient interval at any one sitting upon any particular branch to gain much real benefit from it. So that finally he neither knows much of the experimental facts of any one of the subjects, nor, which is of more importance still, has he gained any training in scientific method or been imbued with any of the modern spirit of scientific inquiry or research.

His weary brain has been enslaved at unpalatable task-work all the two years, grinding up, at the same time, all four of these important subjects so that he may make answer to stock questions upon them at examination time. He is not judged at all by his character as a student known to his teachers, for the good or bad work that he has turned out during that period, or for any talent or originality that he has shown. There is no attempt, nor is there time for any attempt, to allow him to show what subject he loves; indeed, the system is calculated to make him hate them all instead. He must simply grind and be ground to the same stereotyped pattern as all his fellows; he must, in short, read and struggle to pass his Inter. M.B. Ask any of these men what he is doing at any part of the period and you will hear, not that he is studying anatomy or physiology or any of the other subjects, but that he is going up for his "Inter." at such and such a date; the dominant idea is the woeful examination and how best to get through it, and not any attraction for, or interest in, his subjects of study.

For the continuance of this condition of things the teachers, and not the students, are responsible. When we introduce a rational system of studying these subjects, which will teach our students to think, to examine critically the work done by others who have gone before them and to make attempts to proceed farther by themselves, a new era will dawn in which students will take an interest in their work and will rejoice in knowing that they will be judged on what they have been doing throughout their course, and not upon the extent to which they have impaired their memories and intellects by merely memorising the opinions of other men from their text-books and lectures.

Contrasted with the scientific progress of our time, the maintenance of our present system of examinations, and the perversion of the work of our costly laboratories into mere preparation for them, instead of teaching these subjects as a training in scientific observation and research, may truly be described as conservatism run to seed.

If it be granted that our main object ought to be, during these earlier years, to give the student a training in the methods of scientific investigation in the broad field of biology, and not to cram his mind with experimental facts gathered from the text-book or lecture-room, then the system introduced at Harvard of studying one subject thoroughly at a time and, when this has been mastered, from the point of view expressed above, passing on to the next, is undoubtedly a move in the proper direction. This is more especially true in the case of the branches of biological study where a knowledge of one subject is required before another can be advantageously taken up; where there is, so to speak, a definite *natural* order in which the subjects should be taken up. The writer's one experience under our present system, to give an example, is that the first two months or more of attendance on lectures in physiology are absolutely wasted, because the student begins his study of anatomy at the same time as physiology; if he completely finished his anatomy before he came to physiology, and then had all his time for physiology, our task would be much lighter, nor would the student be handicapped at all in his study of anatomy by not having learnt his physiology. Again, he ought to have completed a course on cellular physiology and done all his minute anatomy or histology, including his practical work in histology, before he commences to study the physiology of the mammal.

Further, what advantage accrues from studying a number of subjects at the same time? The student cannot possibly become absorbed in one and grow to enjoy really the study of it, because he feels that his other subjects are becoming cold from neglect. He must, therefore, turn about from one to another, and surely no scientific progress can be made by reading in such a scrappy fashion. The person who can do it with conspicuous success is certainly not the kind of person we want to encourage; yet for such intellectual weeds we arrange a system which chokes out, or does the best that can be imagined to choke out, our choicest flowers. This furnishes a sufficient clue to the well-known observation that our men of highest genius in the past have often been those that the schools rejected, or found no occasion to honour.

The conscientious student who starts simultaneously the study of anatomy, physiology, organic chemistry and materia medica under our present system is surely to be pitied. He hears a lecture in anatomy and tries to take some interest in this; he passes on to one, say, in organic chemistry, and for the time switches his attention off anatomy on to organic chemistry; next he turns his mind to physiology, and finally, weary and baffled, he probably sleeps through a lecture on the preparations of morphia of the British Pharmacopœia. Such intellectual juggling gives the student an acquaintance with the jargon of science, but of scientific method and scientific spirit it most assuredly teaches him nothing.

Every text-book of practical physiology must necessarily be written primarily to suit the requirements of a particular laboratory and a particular teacher, since the types of instrument used in different laboratories vary much, and the selection of experiments chosen by different teachers is also a very variable quantity. Prof. Porter's book has been written to suit the requirements of the Harvard course, and a number of the instruments described have been devised by himself for that course and with a special view of combining economy with efficiency. In nearly all cases, however, the experiments described can easily be adapted to the forms of apparatus used in this country, and the directions are clear and easily followed.

The large number of simple sketches showing the student how to arrange his apparatus is a novel and important feature of the book. This is a great improvement on the usual photographs of apparatus seen in most text-books of practical physiology hitherto published, which are of no service, because the student sees the apparatus on the laboratory table before him, and on the reproductions of tracings, which have little value, since the student obtains copies for himself in the course of his work. In all cases in this book the illustrations are designed to aid the student in understanding what he is asked to do, and are not intended merely for ornament, although they are, at the same time, well drawn and reproduced.

The book is divided into two parts, of which the first treats of the physiology of nerve and muscle, and the second of the circulation of the blood. The first section is much the longer of the two, and includes many experiments which are not usually attempted in this country by the student, but are nevertheless well within his power and very instructive; as examples of this may be cited, the stimulation of involuntary muscle, polar stimulation of the heart, galvanotropism, the effect of calcium salts upon skeletal muscle, idiomuscular contraction, summation of inadequate stimuli, and the stroboscopic method of demonstrating the action current of tetanus. The second section, although shorter, also contains several experiments hitherto novel to the usual student's course.

On the whole, it may be said that the book is clearly written in an original style, and is a welcome departure from the hackneyed treatment of practical physiology which is usually presented to the student.

BENJAMIN MOORE.

AN AMERICAN INTRODUCTION TO BOTANY.

Plant Studies. An Elementary Botany. By John M. Coulter, A.M., Ph.D., Head of Department of Botany, University of Chicago. Pp. vii+392. (London: Henry Kimpton, 1901.) Price 7*s.* 6*d.* net.

DR. COULTER'S work is one of the kind now in fashion, as it is a text-book for beginners that deals argely with the bionomics or œcology of plants. The study of œcology is, beyond doubt, of value to beginners in that it immediately establishes a sympathetic interest in the plant as a living organism, which has wants to satisfy, a policy to pursue and warfare to wage. Yet a scientific survey of a plant's life in relation to environment is, in most respects, possible only after a thorough investigation into the physiology and structure of many plants; in other words, an œcological truth is rarely susceptible of brief and simple proof. Consequently, in placing this branch of the subject before the student at the outset of his studies there is always a danger of cramming the beginner with principles of which no adequate proofs are given, or indeed possible at that stage. In a work of small size like the one before us it was impossible for the author to give proofs of more than a few principles, and he has elected to lay stress rather upon the illustration of principles than upon their accurate demonstration. The work is therefore hardly adapted to serve as an introduction to scientific botany for the use of students working without a teacher's aid; nor does Dr. Coulter intend that it should so serve; he states definitely that the book is intended to supplement the teacher, the laboratory and field-work.

The first 220 pages are concerned in the consideration of the general œcology of plants and of special "societies" (hydrophytes, mesophytes and xerophytes). Though the views expressed are for the most part those to be found in the works of Kerner, Warming and Schimper, there are not wanting cases in which the author enunciates views that are unwarranted; for instance, very dubious in relation to the protection of flowers is the significance of the water reservoirs of the teasel and of *Bilbergia* (p. 136). Lacking in proof, too, is the statement, "In certain parts of the tropics the air is so moist that it is possible for some plants to obtain sufficient moisture from this source, without any soil-relation or water-relation" (p. 98). On p. 123 the term cross-pollination is made to include geitonogamy despite of the different physiological effects of the two processes.

While arousing interest and stimulating a certain kind of intelligent observation, the book hardly encourages close reasoning or accurate language. It is ever a question as to when the rigid precision of technical terms may give place to vague elasticity of more familiar language. And in this respect the author can hardly be congratulated. Such expressions as "earth influence" (in relation to geotropism), "light influence" (in relation to heliotropism), "soil roots," "water roots," "air roots," "soil-related," "leaf-related," "light-relation," "life-relation," "life-process," "seed plants," though strongly reminiscent of the Fatherland, hardly seem to be improvements either on ordinary English or on appropriate technical expressions. At times, indeed, it is not easy to grasp the meaning of some of the sentences; for instance, after telling us that a root "is either an absorbent organ or a holdfast, or very often both," the author continues, "For such work no light-relation is necessary, as in the case of foliage leaves; and there is no leaf-relation, as in the case of stems" (p. 89).

The latter half of the book briefly considers selected groups of cryptogams, and gives an outline of the general characters of "flowering plants," which last Dr. Coult terms "spermatophytes."

Dr. Coulter's work is richly and excellently illustrated, a number of the illustrations being original. For this reason, and, further, because the author touches on questions elsewhere treated only in much larger works, the book may be found useful to such students as can employ it, as Dr. Coulter intends, merely to supplement the theoretical and practical instruction of a competent teacher.

OUR BOOK SHELF.

B. Eyferth's Einfachste Lebensformen des Tier- und Pflanzenreiches. Naturgeschichte der mikroskopischen Süsswasserbewohner. Dritte, vollständig neubearbeitete und vermehrte Auflage. Von Dr. Walther Schönichen und Dr. Alfred Kalberlah. Pp. 700. Taf. 16. (Brunswick: Benno Goeritz, 1900.)

THIS new edition of Eyferth's work will no doubt be of great use to students of microscopical forms of both vegetable and animal life. It includes representatives of most of the European families and genera of minute plants and animals, and there are sixteen excellent photographic plates giving typical illustrations of the genera. The nomenclature adopted for the botanical sections is that of Engler and Prantl in their "Natürliche Pflanzenfamilien," and the authors state that all recent additions to this branch of scientific literature have been taken into consideration, more especially with regard to results and conclusions arrived at by special workers at the various groups. The species enumerated, and to which are appended short descriptions, are stated to be representative ones about which there is no uncertainty of determination; but in the family Desmidiaceæ the species included are by no means representative, many of the very commonest ones being left out in preference for others which are uncommonly rare and hardly likely to be observed by the ordinary student of microscopical forms of life, for which person the book is undoubtedly written. One also wonders at the inclusion of Naegeli's genus *Oocardium* amongst the Desmids, and the presence of such useless genera as *Holocanthum*, *Schizocanthum*, *Pleurotaeniopsis* and *Pleurenterium*, which are introduced directly from Engler and Prantl. A most typical genus of the blue-green algæ—*Gloeochaete*—is placed in the Rhodophyceæ, and so is *Porphyridium*, which has most claim to be regarded as a reddish form of a blue-green, Aphanocapsa-like alga. The animal sections are given rather more completely than the vegetable, but the nomenclature of the Sarcodina seems to be considerably erroneous. The systematic position of *Hydrurus foetidus* amongst the Protozoa is truly remarkable.

G. S. WEST.

Handbook of British, Continental and Canadian Universities, with special mention of the Courses open to Women. Supplement for 1901. Compiled for the Graduate Club of Bryn Mawr College by Isabel Maddison, B.Sc., Ph.D. Pp. 70. (Pennsylvania: Bryn Mawr College, 1901.)

THIS is a supplement to a handbook published in 1896 to show the courses open to women in universities. As practically all European universities and colleges are now open to women, the original title was modified when a new edition was called for in 1899, and the book has become a short guide showing for the benefit of men as well as women the university systems, requirements, &c., of various countries. The present supplement contains corrigenda and addenda, bringing the handbook up to date as regards the lists of professors, lectures and the constitutional changes. Though the book is not to be compared with the Minerva Jahrbuch in point of value for reference, it may be of service to educationists interested in the facilities for the higher education of women.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Subjective Lowering of Pitch.

MR. SHERWOOD (p. 233) seems to have misunderstood my meaning. I did not intend to imply that a singer should be conscious of his own flatness (*i.e.* if loudness causes subjective lowering of pitch), but that his voice, being relatively loud to himself, should sound to him flatter than it really is; and that he would try to counteract the impression by singing sharp. This is the reverse of experience. A singer having a good ear for external music, but singing flat, evidently hears his own voice *sharper* than it really is. Such a singer keeps his voice up better in a chorus, or when the accompaniment is loud enough to produce a subjective impression as strong as that of his own voice.

Malvern, July 14. F. J. ALLEN.

Phototherapy.

As stated in NATURE, July 11, p. 259, Prof. Finsen of Copenhagen proposed, in 1893, that patients suffering from small-pox should be kept in rooms from which the chemical rays of light are excluded by means of red curtains or red glass. He was anticipated in this treatment by John Gaddesden, who wrote the famous medical treatise "Rosa Medicinæ," and died A.D. 1361. He cured a son of King Edward I. of small-pox by wrapping him in scarlet cloth in a bed and room with scarlet hangings. He says of the result, "est bona cura; et curavi eum in sequenti sine vestigio variolarum," "Dict. of Nat. Biogr.," and "Biographie Générale." M. H. CLOSE.

THE CONGRESS ON TUBERCULOSIS.

FOR some time past most elaborate preparations have been made for this Congress, and latterly it was feared that, owing to the postponement that was necessary on account of the death of Queen Victoria, the attendance, especially of workers from abroad, might be seriously affected. Fortunately, this anticipation has not been realised, and from the list of delegates and the number and importance of the papers promised there appears to be every prospect of a most successful and useful series of meetings.

If the work of the Congress was to be of an educational nature, it could scarcely be hoped that much time could be devoted to new work; and that it would be educational in the best sense of the word soon became evident. Certainly few congresses have succeeded in arousing such interest in matters affecting the health and general welfare of the community.

From the King, who gave his patronage, to the numerous municipal representatives and delegates of learned and philanthropic societies all classes seem to be represented; and that the interest aroused is not merely on paper is evident from the list of those who were present at the opening meeting on Tuesday. The Duke of Cambridge presided at the command of the King, and was supported by the American Ambassador and other Ministers and Ambassadors, the Duke of Northumberland, Earls Derby, Cawdor, Spencer and Cadogan, Lord Lister, the Lord Mayor and a whole host of distinguished scientific men. The Colonies were well represented by Lord Strathcona, Sir Andrew Clarke, Sir Walter Peace and others, whilst the Foreign delegates numbered between two and three hundred. The work of bringing a goodly company together had evidently been in competent hands. Will the work of the Congress be equally good? So far this question may be answered in the affirmative; and should the rest of the meetings be as successful as those of the first and second days, the Congress will have thoroughly justified its existence.

The Secretary General in his opening report referred to the Pathological Museum as one of the chief educational works of the Congress, and there can be little doubt that no such collection of tuberculous specimens has ever before been brought together. Every known tuberculous lesion in man and in the lower animals is illustrated, and every bacillus that in the smallest degree resembles the tubercle bacillus is represented. Classical specimens of Potts, Addison and Astley Cooper are all shown, and of specimens of later date a really typical collection has been made. After other features in the history of the Congress had been alluded to by the Secretary General, the Congress was declared open and a telegram was sent to the King. An answer to this telegram, wishing the Congress all success, came before the close of the meeting. The delegates were then addressed by the Marquis of Lansdowne, Earl Cadogan, the Lord Mayor of London, Lord Strathcona and Lord Lister, whose remarks are reported by the *Times* as follows:—

He said they met under immeasurably happier auspices than could possibly have been the case not many years ago. Thanks to the labours of the illustrious man who would address the general meeting on the following day, they now knew the enemy they had to deal with, which before the discovery of the tubercle bacillus was shrouded in impenetrable obscurity. They also knew, thanks to Pasteur, that that microbe was incapable of originating *de novo* in the human body; that, while some constitutions were more prone to its invasion than others, it must always be derived from similar organisms in the external world. Hence there came to be opened up the splendid prospect of the prevention of tuberculosis. But it was by no means only prevention that they were looking at. They also aimed in the present day at the cure of consumption. In this respect matters were very much more hopeful than they had been till quite recently. The physician might learn a great deal in this point of view from the experiences of the surgeon. There were a great many surgical complaints which they now knew to be just as much tubercular as pulmonary consumption—that was to say, they were just as much due to the growth of the tubercle bacillus. Yet the surgeon knew that in many of these cases the disease might be completely cured; that, in consequence of the means—of which they were getting to know more and more every day—which the animal organism had of resisting microscopic invaders, the tubercle bacillus was not only arrested in its progress, but swept away altogether, and the result came to be a healthy state of the tissues and parts in which it was. These experiences showed that tuberculosis was not necessarily an incurable disease. That was an immense point to have demonstrated. Thus, they were not surprised to learn that physicians were coming to look upon the cure of consumption more hopefully than they used to do, by treating it on recognised principles and on the same broad, general lines as surgical tuberculosis. For his own part, as a surgeon, he had had cases of pulmonary disease brought but little under his notice; but he had been surprised, even in his limited experience, at the numerous cases among his own patients in which people who many years ago had consumptive lungs had subsequently become free from all traces of the disease and had lived healthy, robust and useful lives. These cases he ventured humbly to regard as cases of cure of consumption. Then there were attempts now being made by the use of various specific means to deal with consumption even in its more advanced forms. He must not refer to that at the present time further than to say that some of them at least had very promising aspects. They might be sure that these means would be most carefully considered by the Congress, and he need not say how cordially he hoped and anticipated that their deliberations would be fraught with good. There was another point in which he believed the Congress would be useful besides the concentrated wisdom of the eminent men who had come as delegates to take part in it. If the prevention of tuberculosis was to be effectively carried out, the general public must aid the physician and the surgeon in the endeavour. He anticipated that that splendid gathering of scientific men from all parts of the world, meeting under Royal patronage, for which he might venture to express their profound gratitude, would indicate to he public the vast importance of the work they were engaged in and would lead to their cooperation in the endeavour to minimise and possibly eventually to stamp out entirely the greatest scourge of the human race.

Some idea of the standing of the delegates may be gathered from the following list of those who were presented to H.R.H. the Duke of Cambridge, and who spoke, each on behalf of his nation:—Prof. Osler, from the United States of America; Prof. von Schrötter, Austria; M. le Senateur Montefiore Levi, Belgium; Prof. Charles Gram, Denmark; Prof. Brouardel, France; Prof. von Leyden, Germany; Prof. Thomassen, Holland; Prof. Frédéric Koranyi, Hungary; Sua Eccellenza Senator Enrico di Rienzi, Italy; Prof. Holmboë, Norway; Prof. Cortezo, Spain; Prof. Hofmarshal Printzsjöld, Sweden; Dr. Louis Secretan, Switzerland. Greece and Roumania were also represented, as well as the Universities and all the medical societies and public health bodies in the kingdom.

The work of the Congress has been arranged in four sections. In the first all questions concerning the relations of the State and municipalities to the prevention of tuberculosis are to be discussed, and if the number of papers announced is any criterion, little should remain undiscussed at the conclusion of the Congress. The second section deals with medicine, including climatology; the third with pathology, including bacteriology; and the fourth with tuberculosis in animals.

In addition to the purely sectional work, three general addresses will be given. The first of these, by Prof. Koch, of Berlin, dealing with the preventive measures to be taken in connection with tuberculosis, is printed in full in this number; Prof. Brouardel, of Paris, will give the second address; and Prof. McFadyean, of the Royal Veterinary College, the third. Prof. Koch is also announced to open a discussion on tuberculin—a discussion that should be of a very interesting character.

The "social" programme is unusually attractive, but in no way interferes with the efficient working of the important or business meetings of the Congress. We shall watch with interest the further proceedings of the Congress.

THE LIQUEFACTION OF HYDROGEN.

THE liquefaction and solidification of hydrogen form the last of the definite stages, so far, in the progress towards the absolute zero of temperature. To make the account of this stage clear, it will be necessary to compare it briefly with those which preceded it.

During the third decade of the last century, Faraday found that, whereas different substances have different boiling-temperatures at ordinary pressure, or different condensation-pressures at ordinary temperature, the lowest boiling point could be lowered further by reducing the pressure artificially. Thus by exhausting with a vacuum-pump the vapour from a vessel containing solid carbonic acid, he was able to obtain cold intense enough to liquefy a large number of gases exposed to the low temperature and, at the same time, to considerable pressure. This may be called the vaporisation method of cooling. Pictet in 1877 showed how its effect might be intensified by using the cold so obtained by the low-pressure boiling of one substance, such as sulphur dioxide, to condense at high pressure some more volatile gas, such as carbonic acid, the subsequent boiling of which at reduced pressure would produce a further reduction of temperature. The successive falls of temperature obtained in this way have caused this to be known as the cascade system of refrigeration. Pictet himself thought that by this means he succeeded in liquefying and solidifying hydrogen, and, though this was probably a mistake, the method has proved a very useful one. By the choice of more suitable substances, carbonic acid and ethylene, Wróblewski and Olszewski in 1883 succeeded for the first time in cooling oxygen or air to such a low temperature that under moderate pressure it condensed and remained as a visible liquid, of which, when it was allowed to boil at ordinary pressure, a portion remained liquid at a lower temperature. This cascaded vaporisation method, the direct descendant of Faraday's system, was subsequently used by Dewar in improved apparatus on a larger scale, and was the only means of obtaining considerable quantities of liquid air down to 1895. Attempts were made by others than Pictet to apply it to the liquefaction of hydrogen. But the critical temperature of hydrogen, above which no pressure can liquefy it, is so low that even air boiling into a vacuum at, say, -210° C., or solid nitrogen at -225° C., is not cold enough to cool it below its critical point. If an intermediate gas could have been found, with a critical point high enough to admit of its being condensed under high pressure at the lowest temperature of liquid air, and boiling under reduced pressure at a temperature below the critical point of hydrogen, the problem would have been solved. Nature having provided no such gas, Dewar tried to make one by mixing nitrogen and hydrogen, in the hope that, after the manner of oxygen and nitrogen in air, they would liquefy together. Olszewski made a similar attempt with a mixture of oxygen and hydrogen; but no one succeeded in liquefying hydrogen by the employment of vaporisation cooling, though intensified by cascading in four stages.

Meantime, another method of obtaining a cooling effect had been employed. Thomson and Rankine had shown theoretically in 1852, and Giffard practically in 1873, that if compressed gas be allowed to expand in a cylinder doing work against a piston, the work done externally is represented by a corresponding diminution of the heat-energy of the gas. Similarly, if an iron vessel containing highly compressed gas have the valve opened, the contained gas is forcibly driven out against the resistance due to the generation of a very high velocity. The work of driving it out against this resistance is at any moment being done by the expansion of that which remains inside the vessel, and this remaining gas is cooler in virtue of the work so done. This is the cooling of a gas by work-expansion. In 1877 Cailletet made use of this method to give the first definite practical proof that it was possible to liquefy oxygen, then known as a permanent gas. The vessel in which he had it enclosed under high pressure was a strong glass tube of small bore, which was surrounded by liquid sulphur dioxide or nitrous oxide to give the compressed oxygen a preliminary cooling. The opening of a water-valve then allowed the gas to do the work of driving some water forcibly through, and the gas, after this work-expansion, was so much colder that part of it was condensed into a visible, though evanescent, mist or vapour of oxygen. In 1884 Wróblewski and Olszewski applied the same method to hydrogen, using for preliminary cooling the lowest temperature of liquid air under reduced pressure, and obtained a similar result. Thus a combination of cooling by work-expansion with preliminary cooling by cascaded vaporisation succeeded in practically proving that hydrogen could be liquefied, though it was not possible by any such combination to keep, examine and work with liquid hydrogen.

But there is a third method of cooling a gas—that of free expansion. In the case of the iron vessel containing compressed gas, that gas which is at any moment expanding from the valve is found to be colder immediately after expansion than it was immediately before, though it has, in the act of expansion, done no tangible external work such as it does when expanding within the vessel or behind a piston. It has, however, displaced atmospheric air, given itself considerable residual momentum, and overcome the forces of intermolecular and intramolecular attraction. In virtue of this work done, it has undergone some cooling, the cooling of free expansion. This cooling from free expansion is much less for a given change of pressure than that from work-expansion, or that from vaporisation; so much so that Thomson and Joule had proposed no use for it, and great practical authorities, Siemens and Coleman, had declared that nothing could be accomplished by it—a judgment apparently confirmed by the abortive result of Piazzi Smyth's persevering efforts to utilise it. It is obvious, however, that if there were a method of refrigeration in which the cooling could be continually intensified by accumulation, this method would have a great advantage and would lead ultimately to lower temperatures than other methods which had the benefit of greater initial cooling. This proved to be the case with the method of free expansion. In 1894 Hampson proposed to intensify continually the cooling on this method by accumulating in the compressed gas to be expanded all, or nearly all, of the refrigeration produced by the free expansion of previous portions. This was to be done by letting the compressed gas expand through a nozzle or valve from one end of a long tube and making all the gas, when expanded, immediately return over the tube which it had previously traversed as compressed gas towards the expansion-valve. In the course of this return it cools the succeeding portions of compressed gas which are flowing past it inside the tube, so that as they pass to the expansion point they contain all the cooling which has been previously effected. Thus the compressed gas is continually expanding from a lower temperature than before, and is consequeutly reaching, with the added expansion-cooling, a lower temperature than had been reached by previous portions of expanded gas. This intensification goes on until the cooling is great enough to liquefy a small portion of the expanding gas. The losses in this system are due to imperfect interchange of temperature between the compressed and the expanded gas and to the penetration of external heat, so that its performance depends on the efficiency and compactness of the interchanger or counter-current accumulator. This method of obtaining intense refrigeration involves the combination of free expansion of gas (not liquid) with intensification by counter-current interchange. Hampson constructed and worked his apparatus in 1896, and in its present form it begins liquefying air in less than ten minutes without employing auxiliary refrigerants. A process involving substantially the same combination was invented at or near the same time by Linde, who, in 1895, succeeded in liquefying air with it in fifteen hours. His form of apparatus has since liquefied air in two hours, but requires auxiliary refrigeration in the form of ice and salt or a subsidiary ammonia machine.

The special advantage of the Hampson or Linde method for the liquefaction of hydrogen is that it can take gas at an initial temperature from two to three times as high as its critical temperature, and cool it progressively to the point at which it condenses continuously, without the assistance of any substance boiling below its critical temperature—a condition which had been the stumbling-block of the methods employed by Wróblewski, Olszewski and Dewar. With such an appliance available it would seem that the last difficulty in the way of liquefying hydrogen had been removed. Joule and Thomson, however, had observed that hydrogen, on free expansion, instead of being cooled, is actually heated a little. But they had also observed facts which showed how this difficulty could be overcome. The amount of cooling on free expansion varies with the expansion-temperature and with the nature of the gas. Firstly, as to temperature. The lower the initial temperature the greater the cooling for a given degree of expansion, the variation being inversely proportional to the square of the temperature on the absolute scale. Thus, for every atmosphere that the pressure falls in expansion, air at normal temperature is cooled about a quarter of a degree Centigrade. But expanding from three-quarters of that temperature, or $-56°$ C., it is cooled nearly twice as much, or half a degree, for each atmosphere that the pressure falls. And Thomson considered that, if allowed to expand from an initial temperature of 100° C., it would undergo no cooling at all. The differences of cooling for different substances point in the same direction. Joule and Thomson found that gases which are at a lower point in the scale of corresponding states show more cooling on free expansion than others. Thus oxygen, which is not so far above its critical point as nitrogen, shows more cooling; and carbonic acid, which is actually below its critical point, shows much more. It was a reasonable conclusion then that hydrogen also, if it were made a much less perfect gas by being cooled down to a temperature not much above its critical point, would undergo considerable cooling on free expansion. Early in 1896 Onnes calculated that if hydrogen were cooled to $-210°$ C. before free expansion it would be in the same position in the scale of corresponding states as oxygen expanding from $-20°$ C. Now oxygen expanding from $-20°$ is in a very favourable condition for cooling on free expansion, for it can be liquefied by that method from an initial temperature of $+30°$ C., and hydrogen can readily be cooled below $-200°$ C. by air boiling at low pressure.

In 1898 Dewar had an apparatus constructed to work on the principle above described, and succeeded in collecting hydrogen as a stable liquid, thus obtaining temperature which he subsequently estimated by platinum-resistance thermometer at $-238·4°$ C., or 34·6° A., by constant-volume hydrogen thermometer at $-253°$ C., or 20° A. Later, he boiled liquid hydrogen at low pressure and found it to be, like nitrogen and carbonic acid, one of the substances which readily freeze themselves by evaporation. In the solid hydrogen thus obtained he reached the lowest temperature known, which he estimated at from 13° to 15° A.—temperatures confirmed by his subsequent observations by helium thermometer.

Liquid hydrogen has already been turned to useful account in scientific work by Ramsay and Travers in their researches on the rare inactive gases of the atmosphere. For the purpose of obtaining pure neon by a process of fractional distillation, it was necessary to have so low a temperature that liquid hydrogen had to be employed as a cooling agent. To make this, Travers designed an apparatus on the plan described above, to work in combination with a Hampson air-liquefier which they had at their disposal. The plan involved the preliminary cooling of hydrogen by liquid air at low pressure and its further cooling by free expansion with intensification by counter-current interchange. The Dewar form of the apparatus appears, from such descriptions of it as have been published, to be on the same general plan. The Travers apparatus is fully described, with a drawing to scale, in a paper by its designer in the *Philosophical Magazine* for April 1901. For the present purpose a clearer idea of its working will be obtained from a simplified diagram of it, such as is here given. To avoid complexity, the insulation, the joints and many other details have been omitted.

The operation is as follows: hydrogen is compressed in a pump, the plungers of which are lubricated with water, to a pressure of about 200 atmospheres. The lubrication water and any hydrogen dissolved in it or blown off with it pass together from the water-separator by the tube T for further separation at low pressure in a chamber guarded by a water-seal, whence the gas returns by U and O to the gas-holder. The high-pressure gas from the compressor and a drying purifier passes by the tube A through a coil in the vessel B, containing solid carbonic acid in methylated spirit, by which the hydrogen is cooled to $-79°$ C. Thence it passes through the coil C in another vessel containing liquid air, and the temperature is thereby reduced to about $-185°$ C. In the next vessel lower it is reduced, in the coil D, to a temperature below $-200°$ C. by liquid air boiling at reduced pressure. The liquid air for this purpose is admitted, as required, by the valve E from the vessel above; and the low pressure is maintained in the vessel D by an exhaust-pump connected with it by the tube F and the passage R S. The compressed hydrogen at the temperature of low-pressure liquid air then passes through the coil K in the vessel P, forming the counter-current interchanger, and so reaches the expansion-valve M. It is in this lowest vessel that the operation takes place which has made the liquefaction of hydrogen possible. The vessel and coil K have been previously reduced to the temperature of low-pressure air in the following way. The vessel is connected with the exhaust-pump through the annular passage L and the tube F by opening the tap G and closing H. The tap Q at the bottom of the vessel having

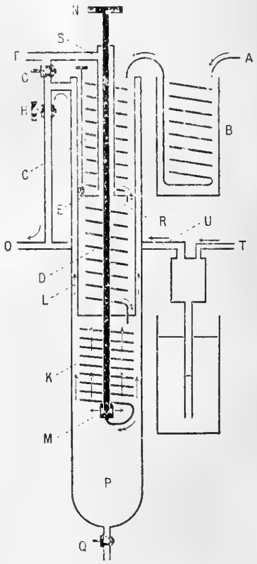

Fig. 1.—A, from compressor ⟶➤ high-pressure gas; M, expansion-valve ⟶, low-pressure gas; O, to gas-holder; F, to exhaust-pump; T, from water-separator of compressor.

been opened, a supply of liquid air is drawn up into the vessel by the suction of the exhaust-pump; and the tap being then closed, the exhaust pressure causes the liquid air to boil at a reduced temperature, cooling the vessel P, the coil K, and the compressed hydrogen within it to about $-205°$ C. The vessel is now cut off from the exhaust-pump by reversing the taps G and H, which remain in the position shown, and the remaining liquid air is drawn off again through Q, which is then closed. The valve M is now opened by turning the spindle controlled by the hand-wheel N, and the hydrogen at about $-205°$ C., issuing into the chamber P, is cooled by free expansion through, say, 10°, to $-215°$ C., and then returns by the passage L and the pipe O to the gasholder. But before doing so it begins the process of intensification by passing over the coil K and giving up to this coil and the high-pressure hydrogen within it the ten degrees of additional cooling below -205° C. which it had gained by expansion. Thus the high-pressure gas which succeeds it reaches the expansion-valve at -215° C., and expanding from a lower temperature gains by free expansion a greater amount of cooling, say 15°, so that it now passes away over the coil at -230° C. and cools to this temperature the compressed gas by which it is succeeded. This intensification proceeds until the cooling reaches the boiling point of hydrogen at the pressure obtaining in P. That pressure is practically atmospheric, since the vessel communicates with the gasholder, which is sealed by a few inches of water. Liquid hydrogen then collects in the lower part of the vessel P.

One of the results of liquefying hydrogen has been to show that helium is a still more volatile gas. It is possible, therefore, to reach a lower temperature than that of liquid—probably even than that of solid—hydrogen by applying to helium the same process of free expansion with intensification by counter-current interchange which has succeeded in liquefying hydrogen. But helium is an exceedingly rare gas, so that the cost of further advances will be very great. Moreover, the most volatile gas probably becomes solid and loses practically all vapour-tension at a temperature above the absolute zero, so that for the attainment of that interesting point no combination of the three methods of cooling above described will suffice. Some fourth system of pumping energy will have to be devised before any portion of matter can be absolutely deprived of heat, and it is for the discovery of this fourth method that onlookers interested in low temperature research are now waiting.

PROFESSOR TAIT.

IN the month of February, Prof. Tait, owing to a lingering illness, resigned the chair of natural philosophy in the University of Edinburgh. Since then the graver symptoms of his illness had somewhat abated, and it was hoped that he might live to enjoy some years of rest and relaxation.

This hope was disappointed by his sudden death on July 4, at Challenger Lodge, Wardie, whither he had been removed for change of air on the invitation of his friend and former pupil, Sir John Murray.

The end of his blameless life and brilliant career brings to many an irreparable gap in their circle of friendship, and to the University of Edinburgh the loss of her chief ornament. Of late years Tait had confined himself more and more to his class work, to the management of the affairs of the Royal Society of Edinburgh, and to the pursuit of his manifold scientific investigations. But, although his direct participation in University affairs diminished, his colleagues never lost the impression that a great man dwelt among them, and not one of them would have dreamed of taking action in a matter likely to interest Tait without considering his opinion. To those who knew him intimately, and therefore loved him, the coming years will never fill his place, although they may alleviate the sense of loss by weaving around it happy memories of flashes of his keen and rapid intellect, of the merry geniality and quaint eccentricity of his singularly beautiful character, and of his staunch, almost quixotic, devotion to an approved cause or to a friend.

Tait was in most senses an Edinburgh man. He was born at Dalkeith on April 28, 1831. His early education was obtained at the Dalkeith Grammar School, and at the Circus Place School in Edinburgh. Like his namesake, the late Archbishop of Canterbury, Tait was a distinguished pupil of the Edinburgh Academy; and loved to tell amusing stories of his mathematical master, Dr. Gloag, whose stern, eccentric character was one of his favourite recollections. At the University he studied for a session under Kelland and Forbes. The former became his colleague and lifelong friend, and he cherished the memory of the latter even in such insignificant matters as the details of class-certificates and class-examinations; and, when the priority or credit of Forbes's work was called in question, he defended him with a ferocious knight-errantry that surprised those who knew Tait little and seemed so characteristic and charming to those who knew him well.

Some of Tait's Academy schoolfellows are still alive, and they speak of him with a mixture of love and respect which shows that he must have been a leading figure among them. Clerk-Maxwell was his most intimate school and college friend, and the friendship thus begun continued to the end of Maxwell's life, absolutely undisturbed by the fact that the two were rival competitors for the Edinburgh chair in 1860. The two men were in truth the Damon and Pythias of British science. Each in his special way was strong in mathematics, both had intense love for physical science, and both were men of wide and varied culture. Each understood perfectly both the strong and the weak points of the other, and both were men of playful disposition and of absolute frankness and sincerity. Those who have occasionally seen letters that passed between them will readily agree that their correspondence should be preserved with a view to ultimate publication; for it would undoubtedly prove one of the most interesting scientific documents of the nineteenth century.

The promise of the two illustrious Edinburgh friends was amply fulfilled in Cambridge. Tait was senior wrangler and first Smith's Prizeman in 1852, being then twenty-one years of age, and Maxwell was second wrangler and first Smith's Prizeman, equal with Routh, in 1854. They were happy in their private tutor, William Hopkins, of whom Tait always spoke with the highest appreciation, and to whose tuition he attributed with characteristic generosity much of the mathematical skill which doubtless came to him by the grace of God. He often contrasted the method and spirit of Hopkins' teaching with the work of the modern coach; but in his depreciation of the latter he perhaps scarcely allowed enough for the brilliancy of Hopkins' pupil and the altered circumstances of the tutor of to-day.

Into the boisterous joviality of Cambridge undergraduate life in his time Tait entered fully, and one often envied the boyish zest with which in middle age he would recall the part he had taken in many a college prank at Peterhouse in his youth. He was, indeed, all his days a sympathiser with the frolics and the foibles of ordinary men, and his stately figure and the genial smile on his rugged, manly face will be as much missed on the green at St. Andrews and in the smoking room of the "Royal and Ancient" as it will be in the quadrangle of the University. Tait was a keen golfer, and for forty years his invariable recreation was an annual holiday at St. Andrews, which he spent mainly on the links. He watched with great delight the triumphal progress to the championship of his amiable son Freddy, and it was said, probably with truth, that Freddy's fame was dearer to him than his own scientific renown. There is little doubt that Freddy's untimely death in the South African war and the agonising weeks of suspense that preceded the final news of his fate hastened the onset of his father's last illness, and it is certain that it darkened the close of a singularly placid and happy life.

In 1854 Tait was appointed professor of mathematics in the Queen's College, Belfast, and there he became acquainted with Andrews the chemist, and through him with Rowan Hamilton the mathematician. These two men exercised a decisive influence on his future life, and, as was his way, he repaid them both with the tenderest regard and reverence. Andrews stimulated his love for well-directed physical research, and helped him to cultivate that marvellous power of clearly apprehending and plainly formulating both the facts and the theories of natural philosophy which was the greatest part of his genius as a physicist. Through the works and personal influence of Hamilton he was led to the study of quaternions—the source and inspiration of his most important contributions to pure mathematics.

In 1860 he was elected to the chair of natural philosophy in Edinburgh, which he was to hold for forty years with ever-increasing distinction. In that time a great army of students[1] has passed through his class room, and few have done so without carrying away with them the image of a great man and a notable teacher. A select number, not a few, have caught some of the original fire of their master and have gone abroad upon the earth to spread his ideas and practise his methods.

Of late years, mainly from want of funds, the laboratory equipment of Edinburgh University has been temporarily eclipsed by grander installations elsewhere; but it must never be forgotten that Tait was one of the first teachers in Great Britain to organise laboratory teaching for his students. Among his first "researchers" were a remarkable trio—Robert Louis Stevenson, William Robertson Smith and John Murray. No man but Tait could have drawn forth and brought together three men so highly distinguished, so utterly different. The popular estimates of the contributions of Murray and Stevenson to science would likely be correct; but it is probably not generally known that Robertson Smith made at least one important contribution to physical science, and was for a time Tait's assistant. He visited his old master regularly as long as he lived, and adored him, as everyone did, without exception, who had once come under his influence.

It appears to have been about the time of his appointment to the Edinburgh chair that Tait first became personally acquainted with Lord Kelvin. Kelvin (then William Thomson) was also a Peterhouse man, but had left Cambridge before Tait came up, and was already, independently and in conjunction with Joule, and concurrently with Rankine and Clausius, writing his classical memoirs on the theory of energy. The first edition of Tait and Steele's "Dynamics," published in 1856, does not, so far as a rapid examination could detect, contain either of the words *work* or *energy*. In its original form it was founded on Pratt's "Mechanical Philosophy," and written on the old-fashioned Cambridge lines, which knew not of Lagrange and Hamilton. Six years later it is on record[2] that in his introductory lecture Tait handled the notions of the "energetic" school with a freedom which bewildered his uninitiated hearers, and laid down the broad lines of a thoroughly modern course of natural philosophy. Probably, therefore, he had come under the influence of Joule and Kelvin before he became personally intimate with the latter. The conjunction with Kelvin produced the famous treatise on "Natural Philosophy," by Thomson and Tait, now familiarly known as T and T′. This wonderful book was published in 1867, and at once began to make a new era in mathematical physics. At first, owing to its highly condensed structure, its influence spread very slowly; but now it would be impossible to find an important treatise, or even a course of college lectures, on natural philosophy that does not show traces of its teaching. The work, it is true, is but a fragment, but the continuation is to be found in dozens of treatises written by men who have been nourished by the strong meat of its serried pages. The collaboration was so perfect that it is not easy to point out the parts due to Kelvin and to Tait.[3] During a somewhat intimate acquaintance, extending well over twenty years, the present writer never heard Tait drop a hint that would enable one to fix on any part of the great treatise as his special work. Its authors always spoke of it and quoted it in an oddly distant way, as if it had been the work of some third person. The two distinguished coadjutors were compelled, by diverging spheres of activity, to dissolve their partnership in T and T′; but, however divided their spheres, they were in scientific aim, as in friendship, undivided to the last.

Since the last paragraph was written, Lord Kelvin has favoured the writer with a note on Tait's early intimacy with himself, and on their collaboration in T and T′. This we reproduce verbatim for the readers of NATURE.

"I first became personally acquainted with Tait a short time before he was elected professor in Edinburgh; but, I believe, not before he became a candidate for the chair. It must have been either before his election or very soon after it that we entered on the project of a joint treatise on natural philosophy. He was then strongly impressed with the fundamental importance of Joule's work, and was full of vivid interest in all that he had learned from, and worked at with, Andrews. We incessantly talked over the mode of dealing with energy which we adopted in the book, and we went most cordially together in the whole affair. He gave me a free hand in respect to new names, and warmly welcomed nearly all of them.

"We have had a thirty-eight years' war over quaternions. He had been captivated by the originality and extraordinary beauty of Hamilton's genius in this respect, and had accepted, I believe, definitely from Hamilton to take charge of quaternions after his death, which he has most loyally executed. Times without number I offered to let quaternions into Thomson and Tait, if he could only show that in any case our work would be helped by their use. You will see that from beginning to end they were never introduced."

Tait's contributions to our text-book literature began with Tait and Steele's "Dynamics," already mentioned. His friend Steele (second wrangler and second Smith's Prizeman in his own year) died early, and wrote but a few chapters of the book. It was so much altered in successive editions that the retention of his name on the title-page became simply a pious tribute to the memory of a friend. The "Elements of Quaternions," begun in 1859, but, in deference to Hamilton, not published till 1867, went through three editions, and along with the "Introduction to Quaternions," by Kelland and Tait (1873), formed, and still forms, the best approach to the science of S, T and ∇. The "Sketch of Thermodynamics" (1868), originating in articles in the *North British Review* (1864), and Balfour Stewart's "Heat" (1866), were for long the only readily available source of information for English readers on the theory of energy, and both contributed powerfully to the growth of the "energetic" school of natural philosophy. "Recent Advances in Physical Science" (1876), a series of popular lectures for professional men, is one of the raciest of his books, and the most useful for the general reader. "Light" (1884), "Heat" (1884) and "Dynamics" (1895), republications of articles written for the "Encyclopædia Britannica," are all models of their kind, clear, forcible and concise, like everything he wrote. Those who wish to have an idea of how Tait taught should read "Properties of Matter," which embodies a considerable part of the course he usually gave to his elementary class.

Although Tait rarely spoke on matters relating to the Unseen, and in general avoided theological controversy, his intimate friends were well aware that he held decided views on such matters. The writer well recollects the grim humour of a Homeric battle at the Edinburgh Evening Club between him and Thomas Stevenson (father of Robert Louis), occasioned by the introduction into the conversation, by some malicious friend, of the

[1] The writer of an excellent notice in the *Scotsman* has estimated the number at about 10,000.

[2] See an admirable appreciation of Tait in the *Glasgow Herald*.

[3] This is almost the only point on which we differ from the writer of the *Scotsman* article.

subject of the Shorter Catechism. It was, therefore, no surprise to some when he and Balfour Stewart proved to be joint authors of "The Unseen Universe" (first printed privately in 1875). This remarkable book reflects the extraordinary width of Tait's knowledge and of his interest in things known and unknown; its success, so far as its immediate object was concerned, is best described by Tait himself in an obituary notice of Balfour Stewart.

"It has passed through many editions, and has experienced every variety of reception—from hearty welcome and approval in some quarters to the extremes of fierce denunciation, or of lofty scorn, in others. Whatever its merits or demerits, it has undoubtedly been successful in one of its main objects, viz. in showing how baseless is the common statement that 'Science is incompatible with Religion.' It calls attention to the simple fact, ignored by too many professed instructors of the public, that human science has its limits, and that there are realities with which it is altogether incompetent to deal."

Tait's scientific memoirs are being republished in three goodly volumes by the Pitt Press, two of which have already appeared. It is therefore unnecessary to do more than allude to the most important of them. The subjects range over pure and applied mathematics and experimental physics. The majority of the mathematical papers are written in the quaternion notation, and this has undoubtedly prevented some of them from becoming so well known as they deserve to be. We may mention specially two papers on Fresnel's wave surface (1859); a series of papers on the properties of "nabla" (∇), and on the linear and vector function, extending from 1867 to 1900; on the rotation of a rigid body about a fixed point (1868)—a paper of great power and elegance, which exhibits Tait's mathematical power at its best; on Green's and other allied theorems (1870), on orthogonal isothermal surfaces (1872); on knots (1877, 1884, 1885), a series of three papers suggested by the problem of the possible configurations of a Thomson vortex atom. In the three classical papers last named he virtually creates a new chapter in the geometria situs, and is brought into relation with the work of Listing, for whom he had the greatest respect. To this subject he returns again in two subsequent papers: a note on a theorem in geometry of position (1880), and on Listing's topologie (1884).

His first experimental work was on ozone, in collaboration with Andrews (from 1856 to 1860). He also began to work with the same distinguished investigator on the compression of gases, but this was interrupted by his removal to Edinburgh in 1860. His memoir on thermal and electric conductivity contains the result of an elaborate series of experiments extending over ten years. The original idea of the method was due to Forbes, but the complete theory and the difficult details are the work of Tait and his pupils. The memoir on mirage is a remarkably elegant and effective combination of experimental and mathematical methods, and is, perhaps, the best example of Tait's work as a natural philosopher. His investigation of the pressure errors of the *Challenger* thermometers was an intricate piece of experimental work extending over several years. It led him into the discussion of the compressibility of liquids, to which are devoted five memoirs (1893–1898). This investigation brought him into close relations with the French physicist Amagat, for whom he had a great regard. Much work is embodied in five papers (1886–1892) on the foundations of the kinetic theory of gases, in which he endeavours to analyse into their logically simplest elements the first principles of a difficult and much-debated subject. His interest in the game of golf produced three important papers on impact (1888–1892), and two on the path of a rotating spherical projectile. On this subject he also wrote a series of popular articles which were widely read and appreciated.

Besides his text-books and original memoirs, Tait contributed assiduously to the current scientific literature of his day. We may mention in particular his article "On Energy" in *Good Words* (1863); his memoirs of Hamilton (*North British Review*, 1866) and of Andrews (along with Crum Brown, 1888); his famous lecture "On Force" (British Association, 1876), so cleverly parodied in Maxwell's poem—

"Ye British asses who expect to hear
Ever some new thing, &c.";

his article "On the Teaching of Natural Philosophy" (*Contemporary Review*, 1878); his fine appreciation of Maxwell's scientific work (NATURE, vol. xxi. p. 317, February 5, 1880), and his various contributions to the ninth edition of the "Encyclopædia Britannica."

Limitations of time and space, and others besides, make it impossible to attempt here any appreciation of the relative importance of Tait's original contributions to the science of the Victorian age. For one thing, the sense of bereavement is too near to us to permit of the necessary historical abstraction. Nor is this the time to enlarge on the polemical discussions in which Tait took part. Ready to take a blow, he did not always spare his strength in giving one, and his opponents did not always relish his rough play. It may be doubted whether many of them carried for long any resulting bitterness; but undoubtedly some of them were led, temporarily at least, greatly to mistake his character. Personal contact with him at once dissipated any such misconception. To feel the magic of his personality to the full it was necessary to visit him in the little room at the back of his house, No. 38 George Square, Edinburgh, the Spartan simplicity of whose plain deal furniture and book-shelves, unpainted, unvarnished, ink-spotted, littered with books and pamphlets and with piles of manuscript bristling with quaternion symbols, was so finely in tune with the tall, rugged figure, the loud, hearty greeting and the radiant, welcoming smile of the kindly host. Ten minutes in that sanctum would have made a friend of his bitterest foe, and the conquest would have been mutual and permanent, for it seemed to be an axiom of Tait's that a man who had become his friend could sin no more. Thither came at various times Joule, Andrews, Kelvin, Stokes, v. Helmholtz, Rankine, Clerk-Maxwell, Balfour Stewart, Rowland, the Wiedemanns (father and son), Adams, Newcomb, Huggins, Newton, Lockyer, Hamilton (at least in the spirit), Cayley, Sylvester, Hermite, Cremona, Clifford, Klein, Bierens de Haan and many more, the majority, alas! now departed like their common friend. It has been the main part of our endeavour to indicate, faintly at least, some of the qualities that attracted and retained such a galaxy of friends; the most potent of all was doubtless the oldest, the simplest ground of liking —he was loved so well because he loved so much.

G. CHRYSTAL.

NOTES.

THE Hughes Bennett laboratory of experimental physiology, which has been added to the University of Edinburgh by Mrs. Cox as a memorial of the work of her father, Prof. J. Hughes Bennett, in connection with medical education, was formally handed over to the University on Saturday last. The addition comprises a large laboratory equipped with appliances for practical work in experimental physiology by individual students, and a small lecture theatre for class demonstrations. The memorial character of the new laboratory is indicated by a bronze bas relief representing Hughes Bennett, which has been executed by Mr. MacGillivray. This is fixed to one of the walls of the laboratory, with an inscription below it commemorating the fact that Hughes Bennett was the first teacher in

Scotland to apply the microscope to the clinical investigation of disease. At the opening ceremony on Saturday, Sir J. Burdon Sanderson, Bart., formerly a pupil of Bennett, delivered an address upon his life and work. Referring to the work to be done in the laboratory, he said, "The laboratory is intended for researches in experimental physiology, by which term was meant the application of the methods derived from physics and chemistry to the investigation of vital phenomena—*i.e.* to the processes which were peculiar to the living organisms. Bennett used to teach in the old days that the scientific method of study was always comparative. It consisted in comparing the unknown with the known, the more complicated phenomena of disease with the simpler ones of health, in bringing their imperfect understanding of vital processes into relation with the clearer notions of natural philosophy. It was thus that physiology, which was at first little more than an introductory study to that of medicine, had been built up into an independent branch of natural knowledge which has its own special aim, the elucidation of the nature of vital processes, but derived its methods of investigation from physics and chemistry. He was sure that all present would cordially join with him in wishing Prof. Schafer success in carrying out the noble purpose to which Mrs. Cox has devoted her munificent gift." Prof. J. G. McKendrick, who was an assistant of Bennett's thirty years ago, proposed a vote of thanks to Sir John Burdon Sanderson, and it was seconded by Sir John Batty Tuke. Sir William Muir, in closing the proceedings, expressed the indebtedness of the University to Mrs. Cox for her munificence.

We regret to see the announcement of the death of Miss E. A. Ormerod, whose studies of injurious insects for many years made her a distinguished authority on agricultural entomology. Miss Ormerod was seventy-four years of age.

The Paris correspondent of the *Times* announces the death of the eminent zoologist, Baron Henri de Lacaze Duthiers, at the age of eighty years. M. de Lacaze Duthiers began life as a medical student in Paris, and in 1854 became professor of zoology at Lille. After his appointment in 1862 to a mission in the Mediterranean, he wrote his famous book "Le Corail." Three years later he became professor of natural history at the Museum, and in 1868 was given a chair at the Sorbonne. In 1871 he succeeded M. Longet at the Academy of Sciences. His activity in the foundation of marine laboratories at Roscoff and at Banyuls-sur-Mer—institutions which were partially endowed by himself—was not the least of his contributions to science.

The council of the British Medical Association has awarded the Stewart prize to Dr. Patrick Manson, F.R.S. The prize was founded by the late Dr. A. P. Stewart, to be awarded biennially for the recognition of important work already done, or of researches instituted, and promising good results regarding the origin, spread and prevention of epidemic disease with a view to encourage the continuance of the same. It consists of an illuminated certificate and a cheque for 50*l.* The Scientific Grants Committee of the Association has allowed 350*l.* for scientific grants and 650*l.* for research scholarships. In the latter sum is included the separate scholarship known as the (200*l.*) Ernest Hart memorial scholarship. The total amount which has been spent in scientific research through this committee since its institution in 1874 is 15,998*l.*, independently of 1650*l.* granted to societies and bodies outside the Association.

In connection with the subject of the subjective lowering of musical pitch, Mr. Harding's theory referring to it (p. 103), and a suggestion made by Mr. E. C. Sherwood (p. 233), Mr. G. W. Hemming thinks the following experiment should be made by some one with the necessary instruments:—"Set siren A to middle C. Set siren B (say) half a tone lower. Sound A loud and B soft. Then by gradually varying the loudness of one of them a point should be reached at which they would appear *to the ear* as a unison. If this cannot be done, there must be some error in Mr. Harding's theory." Mr. Hemming's experiment would test Mr. Sherwood's point, but it does not seem to be able to settle the original statements. "These," writes Mr. Harding, "can easily be tested by means of *one* siren rotating on a table, the ear of the observer being alternately lowered towards, and raised from, the table (which intensifies by its resonance); a point will soon be found beyond which the sound appears flattened."

The *Revue générale des Sciences* for July 15 contains an interesting article by M. André Blondel on oscillographs. The principles of these instruments have already been described in Nature (vol. lxiii. p. 142), more particularly in reference to the various types of bifilar oscillographs worked out by Mr. Duddell. M. Blondel gives descriptions of the two types of instrument which he has himself perfected and used with such great success in his researches on the arc, namely a bifilar oscillograph similar to those of Mr. Duddell and an oscillograph in which the moving part consists of a ribbon of soft iron. In a comparison of the relative merits of the two different types, M. Blondel considers that the bifilar instrument is the more suitable for laboratory work on account of its great sensibility and accuracy, but that the soft iron type is to be preferred for industrial purposes as it is less fragile and more portable. None of M. Blondel's instruments seem, however, to be so compact as the small portable pattern recently shown by Mr. Duddell at the Institution of Electrical Engineers. An ingenious point in the design of M. Blondel's instruments is that the vibrating parts for different purposes—projection or research work—are all made to fit into the same magnet, thus allowing a simple and rapid change to be made according as the instrument is required for one purpose or the other. A continuation of the article, dealing with the application of oscillographs, is promised.

In *Symons's Meteorological Magazine* for this month, Mr. W. H. Dines contributes a paper on the fallacy of one of the explanations given in meteorological works as to the unexplained double diurnal barometer wave. The fallacy referred to lies in assuming that the inertia of the air can act like a containing vessel with only a small hole in it. If a barometer were placed in a sealed vessel, the changes in level of the mercury would follow the changes in the temperature of the air inside, but if a sudden change of temperature occurs in the lower layers of air, or a sudden increase of vapour tension, an oscillation of the barometer would occur, but with only an extremely small period, instead of lasting for hours. The author remarks that warmth reduces the height of the barometer, provided there is time for the upper part of the warmed column to roll off; but could a space be enclosed by a wall reaching to the upper limit of the air, no variations of temperature in the enclosed space could affect the barometer in the slightest degree. A mathematical statement of the question is given for any one who wishes to go into the matter. Dr. Mill gives a short note on the recent extreme heat in New York. The daily maxima do not appear to have exceeded 100° in the shade, but the night minima were frequently more than 80°, so that little difference of temperature was perceptible indoors between day and night. The humidity was also exceptionally high. It is said that special permission was given for people to sleep in the public parks. The worst part of the heat wave was from June 28 to July 4, during which time the deaths in the streets were so numerous that many bodies had to be buried without identification.

We have received from Mr. J. Elster and Mr. H. Geitel an account of their further experiments on electrical dispersion in closed air spaces (*Physikalische Zeitschrift*, No. 38). They, and Mr. C. T. R. Wilson of Cambridge, had previously arrived independently at the result that the air, notwithstanding the exclusion of all known influences that increase its electric conductibility, is by no means a perfect insulator, owing to the existence of ions, and that the rate of dissipation increased beyond its original amount in the course of a few days. A possible explanation of this behaviour seemed to be that dust-laden air is a worse conductor than air which is dust-free; it might be assumed that the increase of conductibility was due to a gradual self-purification of the air by the deposition of the dust-particles. To a certain extent this assumption is correct, but as it appeared doubtful that the dissipation was due solely to the air becoming dust-free, artificial means of purifying the air were tried. A minute description of the apparatus employed is contained in the article in question. The principal result arrived at is that the gradual increase of electric conductibility observed in closed air-spaces up to a certain limiting value can only be very partially due to the deposition of dust, or to variations of humidity. This is shown in a striking manner in the abnormally high conductibility of the air in cavities, and in cellars which have been closed for some time.

SIR W. J. L. WHARTON, K.C.B., the hydrographer, has presented his report upon the Admiralty surveys made during the year 1900, and it is published as a Blue Book. H.M. surveying vessels were all fully employed and good progress was made in each survey; 1167 miles of coast line were charted, and an area of 10,733 miles was sounded during the year. Dr. Fowler and an assistant were taken on board the *Research* in order to carry out, at the request of the Royal Society, zoological investigations in deep water about 150 miles southwestward of Ushant, the object of the observations being the determination of the vertical limits at which various forms of marine life exist. The surveying vessel, *Gladiator*, was taken to Larne Harbour, Ireland, with the view of ascertaining the truth of reports that the Maiden Rocks cause serious local magnetic disturbances. No such effect was, however, found. A chain of magnetic observations for variation was made at sea by the officers of H.M.S. *Rambler*, on the east coast of Africa off Durban, Beira, Mozambique, Zanzibar, Guardafui and the Arabian coast. The observations are said to show that considerable alteration has taken place of late years in the rate of change of the magnetic declination. During a voyage from Albany to Tasmania, H.M.S. *Penguin* obtained deep-sea soundings at regular intervals 130 miles apart. The greatest depth obtained was 3040 fathoms.

THE composition of alloys employed for bronze medals is referred to by Sir W. C. Roberts-Austen, K.C.B., in the report of the Deputy Master and Comptroller of the Royal Mint. He points out that of late years a change has gradually been effected in the metal used for striking medals which are known by the general name of bronze. Until comparatively recently such medals were invariably struck in copper, which subsequently received a superficial coating mainly consisting of oxide of copper, and the medal was said to be "bronzed." Such a "patina" was formerly imparted to the copper medal by heating it in contact with oxide of iron. The Japanese have long shown their remarkable skill as art-metal workers by employing a wet method, by the aid of which a wide range of shades of brown can be imparted to copper. The solutions are used boiling, and a variety of verdigris, known as "Rokusho," and sulphate of copper are their main constituents. The Japanese, moreover, are very successful in imparting a more or less translucent but permanent coating to the copper, which in fine examples of their art reveals the crystalline structure of the metal beneath the "patina." Sir William Roberts-Austen states that in the years 1897–98 more than 28,500 medals, in commemoration of the Jubilee of Her Majesty the late Queen, were so treated, and the specimens which have been preserved in the Mint show no diminution in the brilliancy of the tints which were originally imparted to them. Many European mints are following the Paris Mint in efforts to replace pure copper by copper alloyed with other metals. Analyses of coins of the reign of Hadrian and Trajan show that the alloys contained about 87 or 88 per cent. of copper and 7 to 11 per cent. of zinc, the remainder being made up of tin, lead, iron and silver, with traces of arsenic and antimony. Sir William Roberts-Austen remarks that modern medallists are working with alloys which resemble those from which the coins mentioned were struck, so that the medallist of to-day is returning to the ideas developed in ancient Rome.

A NEW rangefinder, invented by Prof. G. Forbes, F.R.S., was on view at the Bisley rifle meeting. The want of a rangefinder that is portable and workable, that has not more than two per cent. inaccuracy at 3000 yards, and that does not require a telescope so large as to require a stand, is much felt for infantry work, especially with maxims. All these conditions, says the *Times* correspondent at the meeting, are met by the one in question. It consists of a folding aluminium base, six feet in length, which can be folded in the middle and strapped across the back, and a field-glass carried in the usual fashion. The base is a square tube, hinged at the middle. Each half has at each end a doubly reflecting glass prism. The rays of light from a distant object strike the outer pair of these four prisms, are reflected at right angles along each tube, and are then reflected at the two middle prisms into the two telescopes of the binocular, which can be easily fixed to the centre of the base when in use in directions parallel to the original rays intercepted by the outer prisms. By the measurement of the angle between these rays the distance of the object looked at is determined. This angle is measured by two vertical wires, one in each telescope, seen by the two eyes. One of these wires is fixed, the other moved by a micrometer screw until the two wires appear as one at the same time that the object is seen distinctly. The instrument gives the distance, in the hands of an ordinary observer, at 3000 yards to within 60 yards, at 1500 yards to 15 yards. The 6 ft. base folds to 3 ft. 3 in. and weighs under 3 lb.

IN the *Revue générale des Sciences*, Dr. Guillaume, of the Bureau des poids et mesures, discusses the laws of radiation in reference to their application to incandescent mantles. Dr. Guillaume considers that the high intensity of the Auer light is due partly to the fact that the coefficient of radiation of the mantle is exceptionally high towards the blue end of the flame, partly to the temperature of the flame itself being, as the author shows, higher than has been commonly supposed, and partly to the density of the radiating substance being largely in excess of that of the carbon in an ordinary combustion flame. The high temperature of the mantle is probably attributable to the fact that its coefficient of radiation decreases rapidly towards the red end and infra-red of the spectrum, so that the total radiation is relatively small in comparison with the radiation of rays of short wave-length. Dr. Guillaume quotes the work of Messrs. Le Chatelier and Boudouard, and suggests that the coefficient of radiation of the mantles for infra-red rays presents an interesting field of study. It seems probable that as the wave-length increases, the coefficient may decrease to a minimum and may increase again in a region considerably distant from the visible spectrum. The substances used by von Welsbach thus exhibit gaps in an easily explored region of their emission-spectrum, and we may expect to obtain, with little difficulty, results differing considerably from those furnished by the study of substances whose radiation is more nearly uniform.

THE skin of the okapi, the new mammal discovered by Sir Harry Johnston in the Semliki Forest between Lakes Albert and Albert Edward, has been mounted for the Natural History branch of the British Museum by Mr. Rowland Ward, of Piccadilly. For a time it will be exhibited in the North Hall, among the domesticated animals, but will eventually be placed alongside its nearest living relatives, the giraffes, in the lower mammal gallery. The skin and two skulls were recently exhibited by the Director of the Museum at an evening meeting of the Zoological Society, on which occasion the name Okapia was proposed for this very remarkable mammal, the specific title *johnstoni*, previously suggested by Mr. Sclater on the evidence of two fragments of skin, being adopted. As now mounted, the okapi presents a considerable resemblance in form to a small, short-limbed and short-necked giraffe, although furnished with the large ears characteristic of all forest-dwelling animals, and with an absolutely peculiar type of coloration. No such important discovery has occurred since the giant panda (Ælluropus) was made known to the scientific world in the 'sixties of last century. Prof. Ray Lankester's description of this most interesting animal will be anxiously awaited by all naturalists.

WITH no less than seven reports and other technical documents before him, the writer of the article on the "Decay of our Sea Fisheries" in the July issue of the *Quarterly Review* takes a very serious, not to say pessimistic, view of the situation, and deplores the lack of interest in the fishing industry exhibited by Parliament. It is urged that, with far larger interests at stake, we spend much less money on inquiries connected with our fish-supply than other nations, and that the case for interference, based on the falling-off in the yield of inshore-grounds, is fully established. In this respect, indeed, we are suffering from an improvidence which would have been absolutely fatal in other industries; and the one excuse that can be made for legislative inactivity is that our knowledge of the life-history of our food-fishes is at present far too incomplete to permit of the drawing-up of really effectual regulations and amendments. Trawling as now practised is unhesitatingly condemned; while the importance of returning to the sea the spawn of newly-caught fish is strongly urged. There is, however, another aspect of the subject which has received too little attention. This is the great increase which, owing to protection, has of late years taken place in the numbers of our sea-birds. "No one," writes the author, "who has any sense of fairness blames the trout-hatcher for dealing summarily with the herons, otters, chub, pike and eels that invade his stews; and, if it becomes clear that there are no longer fish enough for both ourselves and the cormorants, it may be in like manner necessary to decide that charity shall begin, and end, at home." It may be added that attention is drawn to the value and importance of the researches carried on by the Liverpool Marine Biological Association and kindred bodies.

IN their Report for the year 1900 the executive committee announce that the New York Zoological Society is in a much more satisfactory financial position than it has ever been before, mainly owing to the liberality of the city. It is felt, however, that the Society does not receive adequate support from private citizens, and strenuous efforts are being made to raise the number of members to 3000, the total at the commencement of the present year being just short of 1000. The most important feature in the Report is an illustrated article by Mr. W. T. Hornaday on the wild sheep of America, the main object of this communication being the description of a hitherto unrecognised type inhabiting part of the Yukon valley. For this animal the name *Ovis fannini* is proposed. According to the illustration, it appears nearly allied to the white Alaskan bighorn, but has a large grey saddle on the back.

WE have received from the director of the Missouri Botanical Garden an elaborate paper on garden beans, by Mr. H. C. Irish. It deals with the species cultivated in America of the genera Phaseolus, Dolichos, Vigna, Glycine, and Vicia, and with their very numerous cultivated varieties, which are described in detail. Like so many of our cultivated fruits and vegetables, the scarlet runner and the kidney bean are unknown in the wild state. The broad bean is stated to be a native of Africa, and to be one of the oldest vegetables in cultivation. De Candolle says that it was cultivated in Europe in prehistoric times. The ten plates illustrate the very great variety in the seeds of the same species produced under cultivation.

IN the *Proceedings* of the Royal Academy of Sciences of Amsterdam, Dr. W. Burck has an interesting note respecting a possible provision of nature for preventing hybridisation in plants. He finds from experiment that the pollen-grains of different species vary very greatly in their sensitiveness to the action of the same chemical substance. Thus with some plants a very small quantity of lævulose greatly promotes the emission of the pollen-tubes, while with others it causes the pollen-grains to burst. Saccharose and dextrose have not the same effect as lævulose. He suggests that there may be present in the stigmatic secretion, not only substances which promote the emission of the pollen-tubes in that particular species, but also substances which act injuriously on the pollen of foreign species.

THE interesting discovery by Baron Toll of buried glaciers from the Glacial period, covered with more recent Post-Glacial deposits containing branches and roots of *Alnus fruticosa*, under the 74th degree of latitude, on the Great Lyakhoff Island of New Siberia, has already been mentioned several times in these columns. We have now received the thirty-second volume of the "Memoirs" (*Zapiski*) of the Russian Geographical Society, the first fascicule of which contains Baron Toll's memoir in full, with several interesting photographs. Three of these represent cliffs of glaciers ("fossil glaciers," as Baron Toll describes them), which are masses of ice, not of river ice, or of ice formed in clefts, but undoubtedly of a glacial ice, dating from the Glacial period, and covered with more recent layers of soil; while two other photographs represent layers of soil containing remains of *Alnus fruticosa* and a species of *Salix* deposited above the ice. The branches and the roots of the former are well seen on the photograph, while the catkins which were found by Baron Toll show that these trees, which now do not spread beyond 70° N. lat., grew on the New Siberian islands during the post-Glacial period. As to the mammoth, the rhinoceros and other extinct mammals, it seems impossible, since the researches of Fr. Schmidt, Tcherskiy, Bunge and Toll, not to accept the last author's conclusion, namely: "The mammoths and the other contemporary mammals lived on the spots where we now find their relics; they died out owing to a change in the physico-geographical conditions of the region. The bodies of these mammals, which have not died in consequence of some sudden catastrophe, were deposited in a cold region, partly on river terraces, and partly on the shores of lakes and on the surfaces of the glaciers, and there they were gradually buried in loam. They have been preserved in the same way as have been preserved the masses of ice underneath, owing to a permanent and perhaps increasing cold."

THOSE who are interested in the local antiquities, church and domestic architecture, folklore and antiquarian odds and ends of the counties of London, Middlesex, Essex, Herts, Bucks, Berks, Surrey and Kent, cannot do better than read *The Home Counties Magazine*, in which a number of brightly-written and well-illustrated articles on these various topics will be found.

THE Scottish archæologists should be happy, as they have a very useful bone of contention in the age of the crannog recently discovered at Dumbuck in the estuary of the Clyde. The Rev.

H. J. Dukinfield Astley warmly asserts its Neolithic origin and attacks Dr. Robert Munro for doubting this view. The weighty arguments of Dr. Munro are parried by Mr. Andrew Lang in his characteristic manner. Those who care to see the present position of this pretty quarrel should consult the current number of the *Reliquary and Illustrated Archaeologist*. Doubtless the problem will be threshed out in Section H of the British Association at the meeting in Glasgow in September next.

THE "Picts' houses" of Scotland are a perennial source of discussion to antiquaries, and Mr. David MacRitchie, who has long studied the Pictish question problem, describes in the *Reliquary and Illustrated Archaeologist* (vol. vii. 1901, p. 89) a series of interesting complicated bee-hive huts round which earth has been heaped. Mr. MacRitchie suggests that the series is as follows:—(1) The primitive subterranean "Picts' houses," consisting of one or more chambers and reached by a low narrow gallery. (2) Circular buildings with several chambers round a central one, the walls rising to a height of 12 to 15 feet and culminating in a "bee-hive" roof. (3) Brochs or forts, similar in ground plan to the last, rising as ring-like towers, with staircases in the walls and the central area unroofed.

THE May number of the *Physical Review* contains a good portrait of the late Prof. Fitzgerald, reproduced by photogravure. Dr. Larmor contributes an appreciative notice of the life and work of the lamented investigator, whose death all men of science sincerely deplore.

Feilden's Magazine will celebrate its second anniversary on the first of next month. During its short life it has shown what a good engineering magazine can be, and has maintained a high standard both in its first-class illustrations and in its text, which has been graphic and well up to date. On this account we are glad to express the wish that its future may be long and prosperous.

THE fifth part of "A Manual of Surgical Treatment," by Drs. W. Watson Cheyne, F.R.S. and F. F. Burghard, has been published by Messrs. Longmans, Green and Co. The subject is the treatment of the surgical affections of the head, face, jaws, lips, larynx and trachea, and one of the main divisions is on the intrinsic diseases of the nose, ear and larynx, by Dr. H. Lambert Lack. Dr. A. Whitfield gives an account of the method of removing superfluous hairs by electrolysis. The negative electrode from a battery of about five Leclanché cells is connected with a needle which is introduced into the neck of the hair follicle. The patient is then instructed to grasp firmly the positive electrode, and after a few seconds bubbles of hydrogen can be seen issuing from the mouth of the follicle. Shortly afterwards the needle is withdrawn, and after a moment or two the hair may be pulled out very easily. If the operation has been successful, Dr. Whitfield says that the hair will slide out of the follicle without offering the slightest resistance, and will bring the inner root-sheath with it. About forty hairs can, on the average, be taken out at one sitting.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Mrs. Morrell; a Lion (*Felis leo*, ♂) bred in Ireland, presented by Mr. Rowland Ward; an Alligator (*Alligator mississippiensis*) from Southern North America, presented by Mr. W. S. Foster; four Crossed Snakes (*Psammophis crucifer*), a Rough-keeled Snake (*Dasypeltis scabra*), two Rufescent Snakes (*Leptodira hotamboeia*), five Rhomb-marked Snakes (*Trimerorhinus rhombeatus*) from South Africa, presented by Mr. A. W. Guthrie; five Red-headed Weaver-birds (*Foudia madagascariensis*) from Madagascar, two Yellow-rumped Seed-eaters (*Crithagra sulphurata*) from South Africa, six Waxbills (*Estrelda cinerea*) from West Africa, two Nutmeg Birds (*Munia punctularia*) from India, presented by Mr. E. S. Foot; two Antillean Boas (*Boa diviniloqua*) from St. Lucia, presented by Mr. Walter Graham; an Algerian Skink (*Eumeces algeriensis*) from North Africa, presented by the Rev. F. Jervis-Smith, F.R.S.; two Peba Armadillos (*Tatusia peba*), three Brazilian Tortoises (*Testudo tabulata*), a Blue and Yellow Macaw (*Ara ararauna*) from South America, a Short-billed Toucan (*Ramphastos brevicarinatus*) from Central America, a Reticulated Python (*Python reticulatus*) from the East Indies, six Spiny-tailed Mastigures (*Uromastix acanthinurus*), three Grey Monitors (*Varanus griseus*) from North Africa, deposited; a Lion (*Felis leo*, ♂) bred in Ireland, received in exchange; two Crested Screamers (*Chauna cristata*) from Buenos Ayres, two Hoopoes (*Upupa epops*), European, a White-fronted Amazon (*Chrysotis leucocephala*) from Cuba, two Red Under-winged Doves (*Leptoptila rufaxilla*) from Guiana, purchased.

OUR ASTRONOMICAL COLUMN.

THE TOTAL SOLAR ECLIPSE, MAY 18, 1901.—Since the provisional telegraphic reports immediately after the eclipse there has been little further information as to the exact procedure of the various parties, but an article in the *Times* of July 20, 1901, gives a more comprehensive series of particulars.

Considering the adverse meteorological conditions, the observations in general must be classed as successful, as out of the fifteen stations occupied along the line of totality, determinations of some kind were made at thirteen places. In respect to the special investigations based on the unusually long duration of totality, however, the results are practically useless. Chief among these unsuccessful attempts were the large scale photographs of corona by Prof. Barnard, the spectroscopic determination of the rotation of the corona by Messrs. Newall, Wilterdinck and Baume Pluvinel, and the determination of heat radiation from corona by Dr. Abbott and Prof. Julius.

The photographs of the region round the sun for recording stars, &c., to be used in searching for possible intramercurial planet were more successful, good results being obtained by Prof. Perrine at Padang and Mr. Dyson at Auer Gadang.

The polariscopic investigations were only partly successful; visual observations were secured by Prof. Julius, and a series of photographs obtained by Mr. Newall with a Savart camera.

In the case of the chromospheric spectrum, several observers have secured more or less successful photographs. At Fort de Kock Dr. Humphreys has obtained good spectra of the lower chromosphere, using a concave grating, the whole blue and violet range of spectrum being on a film two feet long.

Mr. Newall, assisted by Lieut. Briggs, used an objective plane grating and obtained a series of spectra with high dispersion over a small range.

Dr. Mitchell also obtained a valuable series of spectra of the flash by means of a grating spectroscope.

Good series of photographs with prismatic cameras were obtained by the Dutch party at Fort de Kock, M. de la Baume Pluvinel, M. Donitch, and also by Mr. Maunder at Mauritius.

Numerous photographs of the corona and surroundings were obtained with various forms of cameras, but it is improbable that any of these taken in Sumatra will show any considerable extension of the streamers, and reliance will have to be made in this branch upon the photographs taken under the more favourable conditions at Mauritius. In Sumatra, series of large scale pictures were obtained with 40-feet lenses by Prof. Nyland, Mr. Perrine and Dr. Humphreys. Prof. Todd failed to even see the corona at Singkep on account of heavy clouds.

From an examination of the plates it is stated that they show a remarkable feature indicating a huge local storm in the eastern equatorial regions, and several bright arches apparently related to marked prominences, especially in the S.E. quadrant.

The duration of totality again appears to have been considerably different from the computed ephemeris time, the observed time in most cases being *shorter*. The Dutch astronomers at Painan report it about eleven seconds, and Mr. Dyson about nine seconds shorter than the almanac duration. Other observers, however, including Prof. Burton and the Fort de Kock party, appear to have found the time of totality longer than was predicted.

A noticeable feature of this eclipse has been the misleading effect of meteorological statistics as influencing the observers' choice of sites for their stations. The eclipse was observed under almost perfect conditions from Padang Pandjang, which is regarded as the rainiest and cloudiest region in Sumatra, while those who camped in the old Solok Fort were the least favoured on the entire coast.

THE TWELVE MOVEMENTS OF THE EARTH.—In the *Bulletin de la Soc. Ast. de France* (1901, pp. 262–266), M. Flammarion gives an interesting review of the various movements by which the terrestrial sphere is known to be affected at the present time. These are due to, or consist of, the following phenomena :—

(1) Rotation, having a period of 24 hours.
(2) Revolution, having a period of 365¼ days.
(3) Precession, having a period of 25,765 years.
(4) Luni-solar gravitation, having a period of 28 days.
(5) Nutation, having a period of 18⅔ years.
(6) Variation of obliquity of ecliptic, about 47″ arc in 100 years.
(7) Variation of eccentricity of orbit.
(8) Change of line of apsides, period about 21,000 years.
(9) Planetary perturbations.
(10) Change of centre of gravity of whole solar system.
(11) General translation of solar system in space.
(12) Latitude variation with several degrees of periodicity.

NEW NEBULÆ.—In the *Comptes rendus* (vol. cxxxiii. pp. 26–28 and 86–88), M. G. Bigourdan gives two further lists of new nebulæ discovered with the west equatorial at the Paris Observatory. The first paper deals with twenty-one objects, observed during the period 1897–1899, copious notes and comparisons with the N.G.C. being appended.

The second list contains similar information regarding nineteen nebulæ observed between 1884 and 1898.

THE SUPPRESSION OF TUBERCULOSIS.[1]

THE task with which this Congress will have to busy itself is one of the most difficult, but it is also one in which labour is most sure of its reward.

I need not point again to the innumerable victims tuberculosis annually claims in all countries, or to the boundless misery it brings on the families it attacks. You all know that there is no disease which inflicts such deep wounds on mankind as this. All the greater, however, would be the general joy and satisfaction if the efforts that are being made to rid mankind of this enemy, which consumes its inmost marrow, were crowned with success.

There are many, indeed, who doubt the possibility or successfully combating this disease, which has existed for thousands of years, and has spread all over the world. This is by no means my opinion. This is a conflict into which we may enter with a surely founded prospect of success, and I will tell you the reasons on which I base this conviction.

Only a few decades ago the real nature of tuberculosis was unknown to us; it was regarded as a consequence, as the expression, so to speak, of social misery, and, as this supposed cause could not be got rid of by simple means, people relied on the probable gradual improvement of social conditions, and did nothing. All this is altered now. We know that social misery does indeed go far to foster tuberculosis, but the real cause of the disease is a parasite—that is, a visible and palpable enemy, which we can pursue and annihilate, just as we can pursue and annihilate other parasitic enemies of mankind.

Strictly speaking, the fact that tuberculosis is a preventible disease ought to have become clear as soon as the tubercle-bacillus was discovered, and the properties of this parasite and the manner of its transmission became known. I may add that I, for my part, was aware of the full significance of this discovery from the first, and so will everybody have been who had convinced himself of the causal relation between tuberculosis and the tubercle-bacillus. But the strength of a small number of medical men was inadequate to the conflict with a disease so deeply rooted in our habits and customs. Such a conflict requires the cooperation of many, if possible of all, medical men, shoulder to shoulder with the State and the whole population; but now the moment when such cooperation is possible seems to have come. I suppose there is hardly any medical man now who denies the parasitic nature of tuberculosis, and among the non-medical public, too, the knowledge of the nature of the disease has been widely propagated.

[1] Paper on "The Combating of Tuberculosis in the Light of the Experience that has been gained in the Successful Combating of other Infectious Diseases," by Prof. Robert Koch, read at the British Congress on Tuberculosis, July 23.

Another favourable circumstance is that success has recently been achieved in the combating of several parasitic diseases, and that we have learned from these examples how the conflict with pestilences is to be carried on.

The most important lesson we have learned from the said experience is that it is a great blunder to treat pestilences uniformly. This was done in former times; no matter whether the pestilence in question was cholera, plague, or leprosy: isolation, quarantine, useless disinfection were always resorted to. But now we know that every disease must be treated according to its own special individuality, and that the measures to be taken against it must be most accurately adapted to its special nature, to its etiology. We are entitled to hope for success in combating tuberculosis only if we keep this lesson constantly in view. As so extremely much depends just on this point, I shall take the liberty to illustrate it by several examples.

The pestilence which is at this moment in the foreground of interest, the bubonic plague, may be instructive to us in several respects.

People used to act upon the conviction that a plague patient was in the highest degree a centre of infection, and that the disease was transmitted only by plague patients and their belongings. Even the most recent international agreements are based on this conviction. Although, as compared with formerly, we now have the great advantage that we can, with the aid of the microscope and of experiments on animals, recognise every case of plague with absolute certainty, and although the prescribed inspection of ships, quarantine, the isolation of patients, the disinfection of infected dwellings and ships are carried out with the utmost care, the plague has, nevertheless, been transmitted everywhere, and has in not a few places assumed grave dimensions. Why this has happened we know very well, owing to the experience quite recently gained as to the manner in which the plague is transmitted. It has been discovered that only those plague patients that suffer from plague-pneumonia—a condition which is fortunately infrequent—are centres of infection, and that the real transmitters of the plague are the rats. There is no longer any doubt that, in by far the majority of the cases in which the plague has been transmitted by ocean traffic, the transmission took place by means of plague among the ship rats. It has also been found that, wherever the rats were intentionally or unintentionally exterminated, the plague rapidly disappeared; whereas at other places, where too little attention had been paid to the rat plague, the pestilence continued. This connection between the human plague and the rat plague was totally unknown before, so that no blame attaches to those who devised the measures now in force against the plague if the said measures have proved unavailing. It is high time, however, that this enlarged knowledge of the etiology of the plague be utilised in international as well as in other traffic. As the human plague is so dependent on the rat plague, it is intelligible that protective inoculation and the application of antitoxic serum have had so little effect. A certain number of human beings may have been saved from the disease by that, but the general spread of the pestilence has not been hindered in the least.

With cholera the case is essentially different; it may, under certain circumstances, be transmitted directly from human beings to other human beings, but its main and most dangerous propagator is water, and therefore, in the combating of cholera, water is the first thing to be considered. In Germany, where this principle has been acted on, we have succeeded for four years in regularly exterminating the pestilence (which was introduced again and again from the infected neighbouring countries) without any obstruction of traffic.

Hydrophobia, too, is not void of instruction for us. Against this disease the so-called protective inoculation proper has proved eminently effective as a means of preventing the outbreak of the disease in persons already infected, but, of course, such a measure can do nothing to prevent infection itself. The only real way of combating this pestilence is by compulsory muzzling. In this matter also we have had the most satisfactory experience in Germany, but have at the same time seen that the total extermination of the pestilence can be achieved only by international measures, because hydrophobia, which can be very easily and rapidly suppressed, is always introduced again year after year from the neighbouring countries.

Permit me to mention only one other disease, because it is etiologically very closely akin to tuberculosis, and we can learn not a little for the furtherance of our aims from its successful combating. I mean leprosy. It is caused by a parasite which greatly resembles the tubercle-bacillus. Just like tuberculosis, it does not break out till long after infection, and its course is almost slower. It is transmitted only from person to person, but only when they come into close contact, as in small dwellings and bedrooms. In this disease, accordingly, immediate transmission plays the main part: transmission by animals, water, or the like is out of the question. The combative measures, accordingly, must be directed against this close intercourse between the sick and the healthy. The only way to prevent this intercourse is to isolate the patients. This was most rigorously done in the Middle Ages by means of numerous leper-houses, and the consequence was that leprosy, which had spread to an alarming extent, was completely stamped out in Central Europe. The same method has been adopted quite recently in Norway, where the segregation of lepers has been ordered by a special law. But it is extremely interesting to see how this law is carried out. It has been found that it is not at all necessary to execute it strictly, for the segregation of only the worst cases, and even of only a part of these, sufficed to produce a diminution of leprosy. Only so many infectious cases had to be sent to the leper-houses that the number of fresh cases kept regularly diminishing from year to year. Consequently the stamping-out of the disease has lasted much longer than it would have lasted if every leper had been inexorably consigned to a leper-house, as in the Middle Ages; but in this way, too, the same purpose is gained, slowly, indeed, but without any harshness.

These examples may suffice to show what I am driving at, which is to point out that, in combating pestilences, we must strike at the root of the evil, and must not squander force in subordinate ineffective measures. Now the question is whether what has hitherto been done, and what is about to be done, against tuberculosis really strikes at the root of tuberculosis, so that it must sooner or later die.

In order to answer this question it is necessary first and foremost to inquire how infection takes place in tuberculosis. Of course, I presuppose that we understand by tuberculosis only those morbid conditions which are caused by the tubercle-bacillus.

In by far the majority of cases of tuberculosis the disease has its seat in the lungs, and has also begun there. From this fact it is justly concluded that the germs of the disease, *i.e.* the tubercle-bacilli, must have got into the lungs by inhalation. As to the question where the inhaled tubercle-bacilli have come from, there is also no doubt. On the contrary, we know with certainty that they get into the air with the sputum of consumptive patients. This sputum, especially in advanced stages of the disease, almost always contains tubercle-bacilli, sometimes in incredible quantities. By coughing, and even speaking, it is flung into the air in little drops, *i.e.* in a moist condition, and can at once infect persons who happen to be near the coughers. But then it may also be pulverised when dried, in the linen or on the floor for instance, and get into the air in the form of dust.

In this manner a complete circle, a so-called *circulus vitiosus*, has been formed for the process of infection, from the diseased lung, which produces phlegm and pus containing tubercle-bacilli, to the formation of moist and dry particles (which, in virtue of their smallness, can keep floating a good while in the air), and finally to new infection, if particles penetrate with the air into a healthy lung and originate the disease anew. But the tubercle-bacilli may get to other organs of the body in the same way, and thus originate other forms of tuberculosis. This, however, is a considerably rarer case. The sputum of consumptive people, then, is to be regarded as the main source of the infection of tuberculosis. On this point, I suppose, all are agreed. The question now arises whether there are not other sources too, copious enough to demand consideration in the combating of tuberculosis.

Great importance used to be attached to the hereditary transmission of tuberculosis. Now, however, it has been demonstrated by thorough investigation that, though hereditary tuberculosis is not absolutely non-existent, it is nevertheless extremely rare, and we are at liberty, in considering our practical measures, to leave this form of origination entirely out of account.

But another possibility of tubercular infection exists, as is generally assumed, in the transmission of the germs of the disease from tubercular animals to man. This manner of infection is generally regarded nowadays as proved, and as so frequent that it is even looked upon by not a few as the most important, and the most rigorous measures are demanded against it. In this Congress also the discussion of the danger with which the tuberculosis of animals threatens man will play an important part. Now, as my investigations have led me to form an opinion deviating from that which is generally accepted, I beg your permission, in consideration of the great importance of this question, to discuss it a little more thoroughly.

Genuine tuberculosis has hitherto been observed in almost all domestic animals, and most frequently in poultry and cattle. The tuberculosis of poultry, however, differs so much from human tuberculosis that we may leave it out of account as a possible source of infection for man. So, strictly speaking, the only kind of animal tuberculosis remaining to be considered is the tuberculosis of cattle, which, if really transferable to man, would indeed have frequent opportunities of infecting human beings through the drinking of the milk and the eating of the flesh of diseased animals.

Even in my first circumstantial publication on the etiology of tuberculosis I expressed myself regarding the identity of human tuberculosis and bovine tuberculosis with reserve. Proved facts which would have enabled me sharply to distinguish these two forms of the disease were not then at my disposal, but sure proofs of their absolute identity were equally undiscoverable, and I therefore had to leave this question undecided. In order to decide it, I have repeatedly resumed the investigations relating to it, but so long as I experimented on small animals, such as rabbits and guinea-pigs, I failed to arrive at any satisfactory result, though indications which rendered the difference of the two forms of tuberculosis probable were not wanting. Not till the complaisance of the Ministry of Agriculture enabled me to experiment on cattle, the only animals really suitable for these investigations, did I arrive at absolutely conclusive results. Of the experiments which I have carried out during the last two years along with Prof. Schültz, of the Veterinary College in Berlin, I will tell you briefly some of the most important.

A number of young cattle which had stood the tuberculin test, and might therefore be regarded as free from tuberculosis, were infected in various ways with pure cultures of tubercle-bacilli taken from cases of human tuberculosis; some of them got the tubercular sputum of consumptive patients direct. In some cases the tubercle-bacilli or the sputum were injected under the skin, in others into the peritoneal cavity, in others into the jugular vein. Six animals were fed with tubercular sputum almost daily for seven or eight months; four repeatedly inhaled great quantities of bacilli, which were distributed in water and scattered with it in the form of spray. None of these cattle (there were nineteen of them) showed any symptoms of disease, and they gained considerably in weight. From six to eight months after the beginning of the experiments they were killed. In their internal organs not a trace of tuberculosis was found. Only at the places where the injections had been made small suppurative foci had formed, in which few tubercle-bacilli could be found. This is exactly what one finds when one injects dead tubercle-bacilli under the skin of animals liable to contagion. So the animals we experimented on were affected by the living bacilli of human tuberculosis exactly as they would have been by dead ones; they were absolutely insusceptible to them.

The result was utterly different, however, when the same experiment was made on cattle free from tuberculosis with tubercle-bacilli that came from the lungs of an animal suffering from bovine tuberculosis. After an incubation period of about a week the severest tubercular disorders of the internal organs broke out in all the affected animals. It was all one whether the infecting matter had been injected only under the skin or into the peritoneal cavity or the vascular system. High fever set in, and the animals became weak and lean; some of them died after a month and a half to two months, others were killed in a miserably sick condition after three months. After death extensive tubercular infiltrations were found at the place where the injections had been made, and in the neighbouring lymphatic glands, and also far advanced alterations of the internal organs, especially the lungs and the spleen. In the cases in which the injections had been made into the peritoneal cavity the tubercular growths which are so characteristic of bovine tuberculosis were found on the omentum and peritoneum. In short, the cattle proved just as susceptible to infection by the bacillus of bovine tuberculosis as they had proved insusceptible to infection by the bacillus of human tuberculosis. I wish only to add that preparations of the organs of the cattle which were artificially infected with bovine tuberculosis in these experiments are exhibited in the Museum of Pathology and Bacteriology.

An almost equally striking distinction between human and bovine tuberculosis was brought to light by a feeding experiment with swine. Six young swine were fed daily for three months with the tubercular sputum of consumptive patients. Six other swine received bacilli of bovine tuberculosis with their food daily for the same period. The animals that were fed with sputum remained healthy and grew lustily, whereas those that were fed with the bacilli of bovine tuberculosis soon became sickly, were stunted in their growth, and half of them died. After three months and a half the surviving swine were all killed and examined. Among the animals that had been fed with sputum no trace of tuberculosis was found, except here and there little nodules in the lymphatic glands of the neck, and in one case a few grey nodules in the lungs. The animals, on the other hand, which had eaten bacilli of bovine tuberculosis had, without exception (just as in the cattle experiment), severe tubercular diseases, especially tubercular infiltration of the greatly enlarged lymphatic glands of the neck and of the mesenteric glands, and also extensive tuberculosis of the lungs and the spleen.

The difference between human and bovine tuberculosis appeared not less strikingly in a similar experiment with asses, sheep and goats, into whose vascular system the two kinds of tubercle-bacilli were injected.

Our experiments, I must add, are not the only ones that have led to this result. If one studies the older literature of the subject, and collates the reports of the numerous experiments that were made in former times by Chauveau, Günther and Harms, Bollinger and others, who fed calves, swine, and goats with tubercular material, one finds that the animals that were fed with the milk and pieces of the lungs of tubercular cattle always fell ill of tuberculosis, whereas those that received human material with their food did not. Comparative investigations regarding human and bovine tuberculosis have been made very recently in North America by Smith, Dinwiddie and Frothingham, and their result agreed with that of ours. The unambiguous and absolutely conclusive result of our experiments is due to the fact that we chose methods of infection which exclude all sources of error, and carefully avoided everything connected with the stalling, feeding and tending of the animals that might have a disturbing effect on the experiments.

Considering all these facts, I feel justified in maintaining that human tuberculosis differs from bovine, and cannot be transmitted to cattle. It seems to me very desirable, however, that these experiments should be repeated elsewhere, in order that all doubt as to the correctness of my assertion may be removed.

I wish only to add that, owing to the great importance of this matter, the German Government has appointed a commission to make further inquiries on the subject.

But, now, how is it with the susceptibility of man to bovine tuberculosis? This question is far more important to us than that of the susceptibility of cattle to human tuberculosis, highly important as that is too. It is impossible to give this question a direct answer, because, of course, the experimental investigation of it with human beings is out of the question. Indirectly, however, we can try to approach it. It is well known that the milk and butter consumed in great cities very often contain large quantities of the bacilli of bovine tuberculosis in a living condition, as the numerous infection-experiments with such dairy products on animals have proved. Most of the inhabitants of such cities daily consume such living and perfectly virulent bacilli of bovine tuberculosis, and unintentionally carry out the experiment which we are not at liberty to make. If the bacilli of bovine tuberculosis were able to infect human beings, many cases of tuberculosis caused by the consumption of alimenta containing tubercle-bacilli could not but occur among the inhabitants of great cities, especially the children. And most medical men believe that this is actually the case.

In reality, however, it is not so. That a case of tuberculosis has been caused by alimenta can be assumed with certainty only when the intestine suffers first—*i.e.*, when a so-called primary tuberculosis of the intestine is found. But such cases are extremely rare. Among many cases of tuberculosis examined after death, I myself remember having seen primary tuberculosis of the intestine only twice. Among the great *post-mortem* material of the Charité Hospital in Berlin ten cases of priminary tuberculosis of the intestine occurred in five years. Among 933 cases of tuberculosis in children at the Emperor and Empress Frederick's Hospital for Children, Baginsky never found tuberculosis of the intestine without simultaneous disease of the lungs and the bronchial glands. Among 3104 *post mortems* of tubercular children, Biedert observed only sixteen cases of primary tuberculosis of the intestine. I could cite from the literature of the subject many more statistics of the same kind, all indubitably showing that primary tuberculosis of the intestine, especially among children, is a comparatively rare disease, and of these few cases that have been enumerated, it is by no means certain that they were due to infection by bovine tuberculosis. It is just as likely that they were caused by the widely propagated bacilli of human tuberculosis, which may have got into the digestive canal in some way or other—for instance, by swallowing saliva of the mouth. Hitherto nobody could decide with certainty in such a case whether the tuberculosis of the intestine was of human or of animal origin. Now we can diagnose them. All that is necessary is to cultivate in pure culture the tubercle-bacilli found in the tubercular material, and to ascertain whether they belong to bovine tuberculosis by inoculating cattle with them. For this purpose I recommend subcutaneous injection, which yields quite specially characteristic and convincing results. For half a year past I have occupied myself with such investigations; but, owing to the rareness of the disease in question, the number of the cases I have been able to investigate is but small. What has hitherto resulted from this investigation does not speak for the assumption that bovine tuberculosis occurs in man.

Though the important question whether man is susceptible to bovine tuberculosis at all is not yet absolutely decided, and will not admit of absolute decision to-day or to-morrow, one is nevertheless already at liberty to say that, if such a susceptibility really exists, the infection of human beings is but a very rare occurrence. I should estimate the extent of infection by the milk and flesh of tubercular cattle, and the butter made of their milk, as hardly greater than that of hereditary transmission, and I therefore do not deem it advisable to take any measures against it.

So the only main source of the infection of tuberculosis is the sputum of consumptive patients, and the measures for the combating of tuberculosis must aim at the prevention of the dangers arising from its diffusion. Well, what is to be done in this direction? Several ways are open. One's first thought might be to consign all persons suffering from tuberculosis of the lungs, whose sputum contains tubercle-bacilli, to suitable establishments. This, however, is not only absolutely impracticable, but also unnecessary. For a consumptive who coughs out tubercle-bacilli is not necessarily a source of infection on that account, so long as he takes care that his sputum is properly removed and rendered innocuous. This is certainly true of very many patients, especially in the first stages, and also of those who belong to the well-to-do classes, and are able to procure the necessary nursing. But how is it with people of very small means? Every medical man who has often entered the dwellings of the poor, and I can speak on this point from my own experience, knows how sad is the lot of consumptives and their families there. The whole family have to live in one or two small, ill-ventilated rooms. The patient is left without the nursing he needs, because the able-bodied members of the family must go to their work. How can the necessary cleanliness be secured under such circumstances? How is such a helpless patient to remove his sputum, so that it may do no harm? But let us go a step further and picture the condition of a poor consumptive patient's dwelling at night. The whole family sleep crowded together in one small room. However cautious he may be, the sufferer scatters the morbid matter secreted by his diseased lungs every time he coughs, and his relatives close beside him must inhale this poison. Thus whole families are infected. They die out, and awaken in the minds of those who do not know the infectiousness of tuberculosis the opinion that it is hereditary, whereas its transmission in the cases in question was due solely to the simplest process of infection, which do not strike people so much, because the consequences do not appear at once, but generally only after the lapse of years.

Often, in such circumstances, the infection is not restricted to a single family, but spreads in densely inhabited tenement-houses to the neighbours, and then, as the admirable investigations of Biggs have shown in the case of the densely peopled parts of New York, regular nests or foci of disease are formed. But, if one investigates these matters more thoroughly, one finds that it is not poverty *per se* that favours tuberculosis, but the bad domestic conditions under which the poor everywhere, but especially in great cities, have to live. For, as the German statistics show, tuberculosis is less frequent, even among the poor, when the population is not densely packed together, and may attain very great dimensions among a well-to-do population when the domestic conditions, especially as regards the bedrooms, are bad, as is the case, for instance, among the inhabitants of the North Sea coast. So it is the overcrowded dwellings of the poor that we have to regard as the real breeding-places of tuberculosis; it is out of them that the disease always crops up anew, and it is to the abolition of these conditions that we must first and foremost direct our attention if we wish to attack the evil at its root, and to wage war against it with effective weapons.

This being so, it is very gratifying to see how efforts are being made in almost all countries to improve the domestic conditions of the poor. I am also convinced that these efforts, which must be promoted in every way, will lead to a considerable diminution of tuberculosis. But a long time must elapse ere essential changes can be effected in this direction, and much may be done meanwhile in order to reach the goal much more rapidly.

If we are not able at present to get rid of the danger which small and overcrowded dwellings involve, all we can do is to remove the patients from them, and, in their own interests and that of the people about them, to lodge them better; and this can be done only in suitable hospitals. But the thought of attaining this end by compulsion of any kind is very far from me; what I want is that the consumptives may be enabled to obtain the nursing they need better than they can obtain it now. At present a consumptive in an advanced stage of the disease is regarded as incurable and as an unsuitable inmate for a hospital. The consequence is that he is reluctantly admitted and dismissed as soon as possible. The patient, too, when the treatment seems to him to produce no improvement, and the expenses, owing to the long duration of his illness, weigh heavily upon him, is himself animated by the wish to leave the hospital soon. That would be altogether altered if we had special hospitals for consumptives, and if the patients were taken care of there for nothing, or at least at a very moderate rate. To such hospitals they would willingly go; they could be better treated and cared for there than is now the case. I know very well that the execution of the project will have great difficulties to contend with, owing to the considerable outlay it entails. But very much would be gained if, at least in the existing hospitals, which have to admit a great number of consumptives at any rate, special wards were established for them, in which pecuniary facilities would be offered them. If only a considerable fraction of the whole number of consumptives were suitably lodged in this way, a diminution of infection and consequently of the sum total of tuberculosis could not fail to be the result. Permit me to remind you in this connection of what I said about leprosy. In the combating of that disease also great progress has already been made by lodging only a fair number of the patients in hospitals. The only country that possesses a considerable number of special hospitals for tubercular patients is England, and there can be no doubt that the diminution of tuberculosis in England, which is much greater than in any other country, is greatly due to this circumstance. I should point to the founding of special hospitals for consumptives and the better utilisation of the already existing hospitals for the lodging of consumptives as the most important measure in the combating of tuberculosis, and its execution opens a wide field of activity to the State, to municipalities, and to private benevolence. There are many people who possess great wealth, and would willingly give of their superfluity for the benefit of their poor and heavily afflicted fellow-creatures, but do not know how to do this in a judicious manner. Here is an opportunity for them to render a real and lasting service by founding consumption hospitals or purchasing the right to have a certain number of consumptive patients maintained in special wards of other hospitals free of expense.

As, however, unfortunately, the aid of the State, the municipalities, and rich benefactors will probably not be forthcoming for a long time yet, we must for the present resort to other measures that may pave the way for the main measure just referred to, and serve as a supplement and temporary substitute for it.

Among such measures I regard obligatory notification as specially valuable. In the combating of all infectious diseases it has proved indispensable as a means of obtaining certain knowledge as to their state, especially their dissemination, their increase and decrease. In the conflict with tuberculosis also we cannot dispense with obligatory notification; we need it not only in order to inform ourselves as to the dissemination of this disease, but mainly in order to learn where help and instruction can be given, and especially where the disinfection which is so urgently necessary when consumptives die or change their residences has to be effected. Fortunately it is not at all necessary to notify all cases of tuberculosis, nor even all cases of consumption, but only those that, owing to the domestic conditions, are sources of danger to the people about them. Such limited notification has already been introduced in various places, in Norway, for instance, by a special law, in Saxony by a ministerial decree, in New York and in several American towns, which have followed its example. In New York, where notification was optional at first and was afterwards made obligatory, it has proved eminently useful. It has thus been proved that the evils which it used to be feared the introduction of notification for tuberculosis would bring about need not occur, and it is devoutly to be wished that the examples I have named may very soon excite emulation everywhere.

There is another measure, closely connected with notification, viz. disinfection, which, as already mentioned, must be effected when consumptives die or change their residence, in order that those who next occupy the infected dwelling may be protected against infection. Moreover, not only the dwellings but also the infected beds and clothes of consumptives ought to be disinfected.

A further measure, already recognised on all hands as effective, is the instructing of all classes of the people as to the infectiousness of tuberculosis, and as to the best way of protecting oneself. The fact that tuberculosis has considerably diminished in almost all civilised states of late is attributable solely to the circumstance that knowledge of the contagious character of tuberculosis has been more and more widely disseminated, and that caution in intercourse with consumptives has increased more and more in consequence. If better knowledge of the nature of tuberculosis has alone sufficed to prevent a large number of cases, this must serve us as a significant admonition to make the greatest possible use of this means, and to do more and more to bring it about that everybody may know the dangers that threaten him in intercourse with consumptives. It is only to be desired that the instructions may be made shorter and more precise than they generally are, and that special emphasis be laid on the avoidance of the worst danger of infection, which is the use of bedrooms and small ill-ventilated workrooms simultaneously with consumptives. Of course the instructions must include directions as to what consumptives have to do when they cough and how they are to treat their sputum.

Another measure, which has come into the foreground of late, and which at this moment plays to a certain extent a paramount part in all efforts for the combating of tuberculosis, works in quite another direction. I mean the founding of sanatoria for consumptives.

That tuberculosis is curable in its early stages must be regarded as an undisputed fact. The idea of curing as many tubercular patients as possible in order to reduce the number of those that reach the infectious stage of consumption, and thus to reduce the number of fresh cases, was therefore a very natural one. The only question is whether the number of persons cured in this way will be great enough to exercise an appreciable influence on the retrogression of tuberculosis. I will try to answer this question in the light of the figures at my disposal.

According to the business report of the German Central Committee for the Establishment of Sanatoria for the Cure of Consumptives, about 5500 beds will be at the disposal of these institutions by the end of 1901, and then, if we assume that the average stay of each patient will be three months, it will be possible to treat at least 20,000 patients every year. From the reports hitherto issued as to the results that have been achieved in the establishments we learn further that about 20 per cent. of the patients that have tubercle-bacilli in their sputum lose them by the treatment there. This is the only sure test of success, especially as regards prophylaxis. If we make this the basis of our estimates, we find that 4000 consumptives will leave these establishments annually as cured. But, according to the statistics ascertained by the German Imperial Office of Health, there are 226,000 persons in Germany above fifteen years of age who are so far gone in consumption that hospital treatment is necessary for them. Compared with this great number of consumptives the success of the establishments in question seems so small that a material influence on the retrogression of tuberculosis in general is not yet to be expected of them. But pray do not imagine that I wish, by this calculation of mine, to oppose the movement for the establishment of such sanatoria in any way. I only wish to warn against the over-estimating of their importance which has recently been observable in various quarters, based apparently on the opinion that the war against tuberculosis can be waged by means of sanatoria alone, and that other measures are of subordinate value. In reality the contrary is the case. What is to be achieved by the general prophylaxis resulting from recognition of the danger of infection and the consequent greater caution in intercourse with consumptives is shown by a calculation of Cornet's regarding the decrease of mortality from tuberculosis in Prussia in the years 1889 to 1897. Before 1889 the average was 31·4 per 10,000, whereas in the period named it sank to 21·8, which means that, in that short space of time, the number of deaths from tuberculosis was 184,000 less than was to be expected from the average of the preceding years. In New York, under the influence of the general sanitary measures directed in a simply exemplary manner by Biggs, the mortality from tuberculosis has diminished by more than 35 per cent. since 1886. And it must be remembered that both in Prussia and New York the progress indicated by these figures is due to the first beginnings of these measures. Considerably greater success is to be expected of their further development. Biggs hopes to have got so far in five years that in the city of New York alone the annual number of deaths from tuberculosis will be 3000 less than formerly. I take this opportunity of most urgently recommending Dr. Biggs' organisation to the study and imitation of all municipal sanitary authorities.

Now, I do indeed believe that it will be possible to render the sanatoria considerably more efficient. If strict care be taken that only patients be admitted for whom the treatment of those establishments is well adapted, and if the duration of the treatment be prolonged, it will certainly be possible to cure fifty per cent., and perhaps still more. But even then, and even if the number of the sanatoria be greatly increased, the total effect will always remain but moderate. The sanatoria will never render the other measures I have mentioned superfluous. If their number become great, however, and if they perfoim their functions properly, they may materially aid the strictly sanitary measures in the conflict with tuberculosis.

If now, in conclusion, we glance back once more to what has been done hitherto for the combating of tuberculosis, and forward to what has still to be done, we are at liberty to declare with a certain satisfaction that very promising beginnings have already been made. Among these I reckon the consumption hospitals of England, the legal regulations regarding notification in Norway and Saxony, the organisation created by Biggs in New York, the sanatoria, and the instruction of the people. All that is necessary is to go on developing these beginnings, to test, and if possible to increase, their influence on the diminution of tuberculosis, and wherever nothing has yet been done, to do likewise.

If we are continually guided in this enterprise by the spirit of genuine preventive medical science, if we utilise the experience gained in conflict with other pestilences, and aim, with clear recognition of the purpose and resolute avoidance of wrong roads, at striking the evil at its root, then the battle against tuberculosis, which has been so energetically begun, cannot fail to have a victorious issue.

THE ROYAL HORTICULTURAL SOCIETY'S LILY CONFERENCE.

ON July 16 the Royal Horticultural Society held a conference on "lilies." Although by no means organised upon the same scale as the meeting was two years ago, when hybridisation was discussed, the one under consideration proved, nevertheless, of some importance and much interest.

An exhibition of lilies was also arranged for the same day and the following one, in the Society's Gardens at Chiswick, where the conference took place. The number of plants shown was not large, but taking into consideration the fact that many species had done flowering, while others were not yet in blossom, the series collected together may be put down as a fairly representative one. Possibly more examples might have been displayed if growers had had a little longer notice given to them.

As soon as the inevitable luncheon was cleared away from the tent, the chair was taken by Mr. H. J. Elwes, F.R.S., who had returned from abroad for the purpose. He was also put down upon the programme to give an address on lilies, discovered or brought into cultivation since the issue of his well-known monograph upon these plants.

The chairman, however, deputed this part of his task to Mr. J. G. Baker, F.R.S., and contented himself with making a series of interesting comments upon the various points alluded to by the different speakers. Mr. Baker's contribution being mostly descriptive, he merely alluded briefly in passing to the lilies discovered and in several cases taken up by horticulturists during the last twenty years.

The plants concerned came chiefly from Upper Burma and Central and Western China. Some of the new martagons, however, were discovered in California and North Carolina. Species from the first-mentioned locality were due to the efforts of Sir Henry Collett, while the Chinese ones were collected by French missionaries and by Dr. Henry, who was present and spoke at the conference.

Among the many species and varieties mentioned, one may allude to *Lilium mirabile*, found by one of the missionaries in Western China, and which is unique among lilies in possessing as it does a centrifugal inflorescence; in all others, the lowermost flowers upon the stalk are the first to open. *L. lowei* was shown to be the same thing as *L. bakerianum*, the latter name having priority.

Dr. Henry, who sent home no less than 13,700 specimens of plants, was the next to speak. He was not able to pay special attention to any one kind of plants, so had nothing very particular to say about the habitats of lilies.

He described a day's journey in Western China as up one side of a mountain and down again into the valley on the other side. This speaker also pointed out that there were thousands and thousands of these valleys, each with its own flora, and that there was ample room in the tracts of country he traversed for a hundred collectors of plants.

After several contributions had been made to the meeting, Mr. George Massee had something to say upon the fungoid diseases to which lilies are liable. The chairman had already pointed out how the scientific man was indebted to the professional horticulturist, who introduced and flowered many species that the former would otherwise be unable to figure from living species when monographing a genus, and, again, how the practical man gains through the work of the botanist. Mr. Massee showed very forcibly how the gardener does not profit as much as he might from the labours of the mycologist. Great intelligence was granted to the horticulturist, but within a certain circle; this did not, however, include an appreciation of many simple methods of prevention. For instance, Mr. Massee pointed out that by merely adding a little kainite or Strasburgh fertiliser the most serious "lily disease," which, when it has once taken a hold, is incurable, can be successfully warded off.

When the whole series of papers is printed, growers of lilies should find much information of use to them, while botanists should be grateful to have their knowledge of the species and varieties of lilies brought once more up to date.

WILFRED MARK WEBB.

THE PROPERTIES OF STEEL CASTINGS.

THE first of a series of papers on the result of researches carried out during several years at the Sheffield University College was read by Prof. J. O. Arnold before the Iron and Steel Institute on May 9.

This preliminary paper dealt only with castings composed mainly of iron and carbon. It was shown that such a composition was unsuitable to meet the demands of engineers. The maximum stress recorded in the series was 32·42 tons per sq. in., associated with an elongation of only 2 per cent., whilst the maximum ductility obtained was an elongation of 46 per cent. on two inches, correlated, however, with a maximum stress of only 19·2 tons per sq. in.

A long series of observations revealed the curious fact that no correlation exists between the densities and mechanical properties of steel castings.

The mechanical influence of annealing at 950° C. and slowly cooling from that temperature is, in the case of iron containing about 0·4 per cent. of carbon, exemplified by the following figures :—

Condition of steel	Elastic limit tons per sq. in.	Max. stress tons per sq. in.	Elongation per cent. on 2 in.	Reduction of area per cent.
As cast... ...	17·22 ...	23·41 ...	6·5 ...	8·4
After annealing..	10·08 ...	24·03 ...	24·5 ...	29·0

The micrographic effect of drastic annealing is shown in the drawing, CC 2, which has been reduced from a 6-inch circle magnified 315 diameters.

The constituents of the steel as cast present an irregular trellis-like pattern of pale ferrite or iron and dark pearlite or steel. In addition, small castings, or small parts of large castings, present curious brown-etching lines of a sulphur alloy,

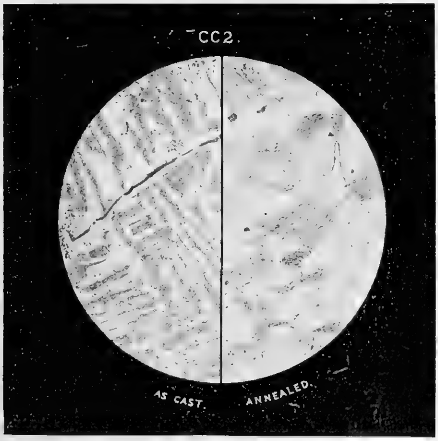

FIG. 1.—Casting CC2. (Reduced from six-inch circle, magnified 315 diameters.)

which arrange themselves almost exclusively along the ferrite, forming lines of dangerous weakness.

After annealing, the long lines of cleavage between the constituents are broken up, large patches of laminated pearlite and allotrimorphic crystals of iron being formed. At the same time, the dangerous lines of the attenuated sulphur alloy are destroyed, segregating into isolated patches. All the above features are well indicated in the micrograph figured. Steel castings often present mechanical discrepancies very difficult to explain, *e.g.* elongations per cent. and bending angles form measures of ductility which might be expected to be proportional to each other, but often such is not the case.

A remarkable feature of the results recorded is the fact that some of the castings built up of very large crystals have presented great ductility, whilst castings with that minutely crystalline structure usually supposed to give the best mechanical results have given unsatisfactory tests.

Considering the fact that such castings were of identical chemical composition and had been subjected to similar thermal treatment, it is difficult to avoid the conclusion that the initial temperature of the steel on casting may exert a permanent mechanical influence, and that consequently the operation of annealing is not thoroughly effective.

SCIENTIFIC WORK IN EGYPT.

SEVERAL matters of scientific interest are described in Lord Cromer's report upon the finances, administration and condition of Egypt and the Soudan. Particular attention is directed to Sir William Garstin's memorandum on irrigation, and to the value of the work of hydraulic engineers in Egypt. Sir William Garstin brings forward observations showing a continuous fall of level of Lake Victoria Nyanza. His remarks upon this fall and the rainfall observations available are here reprinted.

"*Lake Victoria Nyanza Rain Gauges.*—Information regarding the daily rainfall and the lake levels is now regularly received in Egypt from Uganda. The first series of registers, previous to the rebellion, dates from June 1, 1896, to July 31, 1897. The second series commences on September 1, 1898, and has been carried on to October 31, 1900. Unfortunately, it is impossible to connect the two series, as the gauges erected subsequent to the rebellion are not the same as those which formerly existed. We have, therefore, only twenty-six months of observations upon which to base possible theories. This is not sufficient, more especially as we are still ignorant of many important factors bearing upon the relations of the levels and rainfall of the equatorial lakes with the Nile supply. Information regarding the most important point of all, viz. the Albert Nyanza Lake, is still entirely wanting. This is much to be regretted, as this lake, which drains an enormous catchment area, and through the northern end of which passes the water coming from the Victoria Lake, is probably the most important of the reservoirs which feed the White Nile. It is to be hoped that early measures may be taken to erect gauges upon the Albert Lake and to observe them regularly. The records thus obtained would be invaluable to Egypt.

"The following facts, elicited from the rather meagre information at our disposal, may perhaps be of general interest :—

"Two observing stations now exist on the Victoria Lake, one on either side, viz. at Port Alice or Entebbe and at Port Victoria or Ugowe. Unfortunately, the rainfall register for Entebbe only commences from the month of April 1900, so a comparison between the two for the whole year is impossible.

"The Ugowe rain gauge record shows that 46·28 inches of rain fell in the twelve months ending with October 1900, that there were 131 rainy days, and that the storms invariably took place either in the afternoon or at night. Further, that February was the wettest month of the year and July the driest, 6·45 inches being registered for the former and 1·56 inches for the latter. It would also appear that the period of the heaviest rainfall is from November to May. The total rainfall for the six months in question was 30·73 inches, the remaining six months being responsible for only 15·55 inches.

"The rainfall at Entebbe, on the opposite side of the lake, was, so far as the records go, considerably heavier than at Ugowe. The total fall between April and November 1900 was 30·39 inches at the former place, as against 20·59 inches at the latter. As regards the rise and fall of the water surface of the lake it is possible to make a comparison, as registers have been supplied regularly from both stations. . . .

"The records, as far as they go, seem to prove that the lake is always at its lowest in October, *i.e.* at the end of the dry season, and at its highest in December or January. They also show that the lake level has been steadily falling for the last three years, thus :—

	Port Alice (Entebbe). Ft. in.	Port Victoria (Ugowe). Ft. in.
Lake levels on October 1, 1898 ...	3 2 ...	3 2½
,, ,, 1899 ...	2 6½ ...	2 2
,, ,, 1900 ...	1 7 ...	1 1

"It is possible that this fall in the levels may be, in some measure, due to degradation of the bed of the river in the channel whence it issues from the lake; but it seems to be far more probable that it has been caused by a failure of the rainfall over an immense area. All reports go to show, and all travellers who have visited these regions relate, that a severe drought has prevailed over a large portion of Central Africa during the last two years. This drought has extended as far north as the Egyptian Soudan.

"Although it may seem likely that the Nile flood of 1901 will be a poor one if these figures are correct, it would be misleading to attempt to draw any definite conclusions from them. The register of the rainfall only dates from a very recent period, and consequently no comparison can be made with the fall of previous years. Again, the available knowledge of the many factors, which together combine to produce the annual rise of the White Nile, is at present extremely scanty.

"Lastly, as has been already stated, the Albert Nyanza Lake must exercise a most important influence upon the volume of the river, but no attempt has as yet been made to collect information regarding it. It is most desirable that a regular register of its levels and its rainfall should be commenced and maintained as soon as possible."

The Sudd in the Bahr-el-Gebel.—Major Peake's sudd-cutting party removed, in all, fourteen blocks of sudd during 1900. Some of these blocks were, in places, a mile in length and from 15 to 20 feet in thickness. The surface of the river channel was completely closed, and the stream passed underneath the sudd with a high velocity. Sir William Garstin remarks that a visit to the work changed many preconceived ideas as the nature of the obstruction. Instead of the sudd being, as had been supposed, a tangle of weed floating on the water and descending a few feet below the surface, it proved, in most cases, to be a mass of decayed vegetation, papyrus roots and earth, much resembling peat in its consistency, and compressed into such solidity by the force of the current that men could walk over it everywhere, and even elephants could, in places, cross it without danger. The most effectual method of removing it was found to be by cutting deep trenches on the surface, thus dividing it into rectangular blocks of some 10 feet square. These were hauled out, block by block, by means of chains and wire hawsers attached to the gun-boats.

Two portions of the Bahr-el-Gebel still remain uncleared. The one commences at 140 miles south of Lake No, and is some 25 miles in length. The other is some 52 miles further south and about three miles long. In both instances the true channel of the river is blocked by sudd, and it now follows a false channel; in the former instance it passes through a series of broad, shallow lakes.

Survey of the Cataract Region.—Lord Cromer states that the construction of the Nile Reservoirs is now so far advanced that the time has arrived when further studies of the river may usefully be made, so that, should it eventually be found necessary to still further augment the water supply of Egypt, the requisite information for the preparation of the project, or projects, shall be at the disposal of the Ministry of Public Works. One of the first steps necessary to attain this end is to make an accurate survey of the Nile Valley where it passes through the cataract region south of Wady Halfa. It may eventually be decided that a second reservoir is not the best means of supplementing the summer volume of the river, but that it will be more advisable to obtain it by regulating the outlets of the Equatorial and Abyssinian Lakes, by opening up the Bahr-el-Gebel, or some other large scheme. Until, however, a thorough knowledge of the river, as a whole, has been obtained, it would be premature and unadvisable to take any decision whatsoever. The present work is a commencement in this direction, and even should the results obtained, as regards the construction of another dam, prove to be negative, the information thus acquired will be invaluable to those charged with the control of the river.

It is proposed, therefore, to survey the cataract region, at the same time running lines of levels up the river valley. A geological surveyor will accompany the party. It is calculated that three years' work will be required to complete it as far south as the head of the third cataract.

Meteorological Department.—The Observatory, situated in the Abbassieh quarter of Cairo, was greatly improved during the course of last year. The equipment of a first-class meteorological observatory is now working there regularly. The time-ball at Port Said is dropped daily at noon by a current, working automatically, which is sent from the Observatory. Those at Cairo and Alexandria were to commence working early this year. The time of the 30° meridian east of Greenwich has been made civil time for the whole of Egypt, replacing the various local times previously in use.

Eight stations between Alexandria and Omdurman now take regular meteorological observations and send telegraphic weather reports to Cairo daily at 8 a.m. These are printed and published. Arrangements have recently been made by which similar telegraphic reports are daily exchanged at 8 a.m. between Alexandria, Malta, Brindisi, Trieste and Athens. These telegrams are posted for general information at the ports of Alexandria and Port Said.

The observations of all meteorological stations are printed and published monthly. The complete results of the work at the Central Observatory will be published shortly. The observations registered in 1899, together with the mean values of the preceding thirty years, are already printed and ready for publication.

Besides Omdurman, where there is a complete set of instruments, the stations of Rosaires, Fashoda, Wad Medani and Kassala now record rainy days and approximate fall. They have not yet been furnished with proper rain gauges. It is hoped that before long observing meteorological stations may be instituted at different points on the Blue and White Niles.

Funds have been granted for transferring the Central Observatory to Helouan, fifteen miles south of Cairo. The new building will be commenced this year. A set of thermometers has been sent to the base camp at Meshra-er-Rek, in the Bahr-el-Ghazal Province, to be registered and observed there daily.

Geological Survey.—The staff of the Geological Survey has been employed in compiling the results of the previous three years' field work. Reports on the oases of Kharga, Dakhleh and Farafra are on the point of being published; five other reports are ready for printing. Good progress has been made with the preparation of the maps, some of which will shortly be ready for publication. A geological museum is in course of construction, and will probably be completed before the end of the year. The expenditure on this building up to the end of last year was about £E. 2700.

The Preservation of Game.—Captain Stanley Flower, director of the Gizeh Zoological Gardens, is frequently asked questions as to the regulations existing for the preservation of game in the Soudan. The following statement from the report supplies information upon these matters.

A system of licenses for non-native sportsmen has been introduced. The licences are of two kinds: one is issued at £E. 25 and known as licence "A," authorising the shooting of every kind of game except a small class which is absolutely protected, the other issued at £E. 5 and known as licence "B," from which the rarer kinds of game are excluded. In addition to the licence fee of £E. 25, the holder of a licence "A" is required to pay a fee for each animal included in Class 2 which he may kill. A higher charge is made for female animals, but no female animal of the kind included in Class 2 may be knowingly shot. In the case of elephants the royalty upon ivory is also payable.

The Wild Animals Preservation Ordinance, 1900, also provided that natives might be requested to take out licences, but this provision only applies in districts where it is specially brought into force by a notice issued by the Governor-General. The terms of the licences are arranged by the licensing officer. This part of the Act has been brought into force as regards Kassala, and licences have been granted to the Sheikhs of two or three tribes to kill or capture a limited number of the bigger kinds of game. They pay nothing for their licence, but are required to inform the Mudir if they kill or capture any elephant, giraffe, buffalo or certain other kinds of game and to pay a fee varying from £E. 1 to £E. 8; as there is usually a demand at Kassala for specimens of wild animals, it is thought that the natives will readily pay the fees.

Several specimens of wild animals have been exported during the year, and there is also a certain traffic in skins and trophies. There was reason to fear that, unless the trade was controlled, it would lead to unnecessary destruction of the rarer sorts of animals. The Wild Animals Preservation Ordinance, 1901, which has been recently promulgated, places the export of wild animals and birds under Government control.

Section 2 prohibits the export of wild animals and birds, or of their skins, feathers, horns and trophies in an unmanufactured condition other than elephants' tusks, rhinoceros horn and ostrich feathers, except under Government permit. The provision does not apply to animals or birds which are killed under a game licence.

The Governor-General is empowered to permit the export of animals and birds of which there is no reason to fear the destruction and to impose a tax upon the same. Arrangements have been made to establish a special department of the Government under the general superintendence of Captain Flower, the Director of the Gizeh Zoological Gardens, to deal with questions relating to the wild animals and birds of the Soudan. Licences to export live specimens will be issued by this Department at fees to be determined later, and the Department will undertake the supply of specimens to Zoological Gardens, Museums and others.

Zoological Gardens.—Specia attention has been paid to the fauna of the Nile Valley. There were in the Gardens in October last 670 animals, representing 169 species, as compared with 473 animals, of 132 species, at the corresponding date in 1898. The most important acquisitions have been a giraffe, presented by Lord Kitchener, and a white oryx, from Kordofan, presented by Sir Reginald Wingate.

The staff of the Gardens was mainly employed during the year in rebuilding and repairing cages. An elephant-house has been built, and plans are being prepared for a new lion-house.

Nile Fish Survey.—The collecting of fish was, during the early part of the year, extended as far as Abu Hamed, and at present Mr. Loat, the specialist selected by the authorities of the British Museum, is working on the White Nile. A considerable number of plates, which will eventually be published, have been printed, and material from which others may be drawn has been obtained. A severe loss was sustained last year in the death of Dr. John Anderson, F.R.S., whose knowledge and experience made his advice of the greatest value in carrying out a work which was taken in hand owing to his initiative.

Egyptology.—Under the very capable direction of M. Maspero, a great improvement has recently taken place in the working of all branches of the Archæological Department. Notably, the appointment of two English inspectors-in-chief has done much to preserve the monuments, both in Lower and Upper Egypt, from further depredation and mutilation.

Work has been proceeding at Karnak. It will be remembered that eleven columns in the Great Hall fell to the ground during the flood of 1899. Five further columns appeared to be in some danger of falling. Under the direction of MM. Legrain and Ehrlich, these columns have now been dismantled; others have been strengthened and repaired. The *débris* of the stones which had fallen has been removed, labelled and arranged in such a manner as to render it possible, should it ever be decided to rebuild these columns, to replace each separate stone in the precise position which it formerly occupied.

Lord Cromer says he has been informed, on high technical authority, that, in spite of every precaution, the remaining portions of this splendid monument of antiquity will of necessity be exposed to considerable risk every year at the period when the subsoil water is falling. A very heavy expenditure of money would, without doubt, minimise this risk, but it is doubtful whether, under any conditions, it will be possible to obviate it completely.

The bases of the columns are of insufficient strength; the soil is unstable; each column supports an immense weight in the shape of roofing-blocks; and the whole structure has been erected without mortar and without bond of any sort.

The principal tombs at Thebes have been closed by gates. The tomb of Amenophis II. has been so arranged that the Royal mummy remains *in situ*, and can be seen by visitors. M. Maspero is studying a project for lighting these tombs by electricity, so as to obviate the destruction to the wall paintings caused by the candles used by visitors.

Technical Education.—The only important technical school in Egypt is that situated in the Boulac quarter of Cairo. The School of Agriculture is a very popular institution, and is rendering good service to the country, but more institutions of this kind seem to be needed.

Lord Cromer refers particularly to the educational needs of Egypt, and suggests that attention should be given to technical education in all its branches. He has discussed this subject with various authorities in Egypt, and finds a general disposition to do something towards the improvement and extension of technical instruction. Mr. J. Currie, director of education in the Soudan and Principal of the Gordon College, has reported upon the subject, and extracts from his report are given by Lord Cromer. It is proposed to establish a large industrial school at Khartoum, to be worked in connection with the Government dockyards and workshops. It is also proposed to find house-room for, and supervise, the following institutions at Gordon College, so far as that can be possible: (*a*) A general Soudan reference library; (*b*) an economic museum, to assist in the commercial development of the country; (*c*) a meteorological station and a small observatory; (*d*) a small analytical laboratory.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MISS E. S. BARCLAY has bequeathed to Bedford College the sum of 1000*l.* without conditions.

WE learn from *Science* that Pittsburg will probably soon have a great technical institution, especially adapted to its needs and as complete in the industrial field of education as the Carnegie Institute of that city has become in art and æsthetics. An advisory committee appointed to determine the best plan and most suitable scope of the new institution has just presented its report to Mr. Carnegie. These expert advisers were Dr. R. H. Thurston, Director of Sibley College, Cornell University, Prof. J. B. Johnson, Dean of the College of Engineering, University of Wisconsin, Prof. Thomas Gray, of the Rose Polytechnic School, and Prof. V. C. Alderson, of the Armour Institute. The scheme proposed includes three different and distinct forms of school which may be combined as parts of one complete technical university. If the whole scheme is accepted by Mr. Carnegie, there will be, in the first place, a first-class technical college. "This college," says the committee, "should be made attractive to the greatest scholars in the fields of physical and chemical science. To obtain and hold such men they must be given ample opportunities for research. This college must be supplied, therefore, not only with great experimental shops and laboratories for students' use, but in all departments there should be splendidly equipped laboratories of investigation and research, under the direction of the head of such department, and with a full corps of assistants for the carrying on of all lines of investigation which are now partly or wholly unprovided for in America." There will also be a Technical High School to carry on work above that of the public grammar school, and day and evening classes for the benefit of those who are unable to take advantage of the more complete courses in this school. Mr. Carnegie has now to decide whether he will found a school for artisans, a technical high school or a technical college, or, if his ambition mounts so high, a true technical university including them all.

AN article by Mr. J. B. C. Kershaw in the July number of the *Monthly Review* contains a few facts which should be of interest to all who are concerned with educational and national progress. He points out that technical education as at present carried on in this country is chiefly instrumental in giving to great numbers of young people elementary instruction in every subject except the dead languages. In the opinion of practical men, this smattering of science and other subjects is of no value from an industrial point of view, and as a system for bringing the few who possess undoubted ability or genius to the front it is costly and unnecessary. In England the aim has been to educate the rank and file of the workers, but the German aim is to educate thoroughly all who are to occupy posts of authority in manufactures and industries. Herein there is a great difference, and many people are beginning to see that the German method is the best when industrial progress is taken as the criterion. The reason lies in the ability to appreciate new developments, or, as Mr. Kershaw puts it, "a thorough scientific training enables the manufacturer to decide quickly upon the merits of the new processes or inventions, and he is not daunted by the fact that in this newly-chosen path of industrial progress there is no 'practical experience' to guide his steps. The German manufacturer has, therefore, been assisted by his own thorough technical training, and by that of his manager, engineer or chemist, in adapting himself more quickly than his English rival to new conditions of trade, or to the exigencies of new processes and new developments of industry." There is little hope of substantial improvement while our manufacturers and commercial men, as a rule, have so little sympathy with scientific work. Their general attitude is reflected in advertisements of this kind—"Wanted, young man as Chemist at Tar and Vitriol Works in North of England; willing to fill up time at Bookkeeping." While trained chemists are considered to be on about the same level as a clerk and inferior to a skilled operative, how can we expect to make advances similar to those which Germany and the United States are making?

SOCIETIES AND ACADEMIES.

LONDON.

Royal Microscopical Society, June 19.—Mr. William Carruthers, F.R.S., president, in the chair.—Mr. T. H. Powell exhibited *Coscinodiscus asteromphalus* under a new 1/40th-inch apochromatic oil immersion objective.—Mr. J. W. Gordon read a paper entitled "An examination of the Abbe diffraction theory of the microscope," in which he stated that the above long-accepted explanation of the phenomena of high-power microscopic observation had been accepted on insufficient proof and would not bear the test of critical examination. The Abbe theory claimed that pictures formed by the microscope of very minute objects were due to diffraction images originated by the object, and that when the oblique rays of light in which these diffraction images existed were excluded, no image of the object was possible. This theory had been experimentally illustrated by Prof. Abbe by means of a grating on the stage of the microscope and a series of diaphragms behind the microscope object glass with slits to partially exclude oblique rays. Mr. Gordon showed that although in favourable circumstances diffraction effects were produced by fine objects on the stage of the microscope, these effects did not appreciably influence the formation of the image. He also showed that the experimental results produced by the above-mentioned diaphragms, which were adduced to prove the theory, were due to a diffraction effect produced by the diaphragms themselves and not by the grating on the stage of the microscope, the same results being obtained with an aërial image of a grating projected upon the stage by a lens in place of the actual grating. He maintained that in the microscope, as in the telescope, it was necessary to eliminate diffraction effects as far as possible by making lenses of large aperture, and not, as in Abbe's theory, to include as many diffraction phenomena as possible. Diagrams in illustration of the paper were thrown upon the screen, and the various experiments referred to were exhibited under a number of microscopes. In the discussion that followed, Prof. S. P. Thompson agreed with Mr. Gordon in rejecting the presentation of the Abbe theory given by Naegeli and Schwendener, but found himself at variance with Mr. Gordon on almost every other point, and proceeded to discuss several conclusions arrived at in the paper.

PARIS.

Academy of Sciences, July 15.—M. Fouqué in the chair.—Determination of three principal optical parameters of a crystal, in magnitude and direction, by the refractometer, by M. A. Cornu. Though the measurement of the three principal indices of a crystal is relatively easy, the determination of the three principal directions involves calculations too intricate for ordinary work. A geometrical study of the total reflection at a crystalline surface has led the author to some analytical relations upon this application of the refractometer, of unexpected simplicity. Numerous observations of crystals with an Abbe refractometer have shown that the formulæ developed are exact within the limits of error of the experimental results. Large clinorhombic crystals of commercial tartaric acid have been used in the experiments to test the formulæ. The demonstration of the formulæ and the numerical results are reserved for a future communication.—On the morphology and position of flagellated parasites with undulating membrane, by MM. A. Laveran and F. Mesnil. The characteristics of organisms of the two genera Trypanosoma and Trichomonas are described and compared, and the distinctive features are defined. The former genus comprises all the flagellated parasites which have been found in the blood of vertebrates.—Can poisoning be caused, through the skin and mucous membrane, in a medium which has been rendered irrespirable by sulphuretted hydrogen? by M. A. Chauveau. Experiments with dogs have shown that, provided an inhaling apparatus is worn upon the head, no ill effects ensue, even if the body of the animal is in an atmosphere charged with sulphuretted hydrogen so as to be poisonous.—On the sugars from blood, by MM. R. Lépine and Boulud. In the blood of dogs fed upon meat, or fasting, a sugar has been found analogous to saccharose, but differing from it in some properties.—On a new joint with variable angle, by M. G. Koenigs.—On the extension of the Riemann method of integration, by M. J. Coulon.—On the solution of equations of elasticity, in the case where the values of the unknowns at the limit are known, by MM. Eugène and F. Cosserat.—On the movement of a pendulum in a resisting medium, by M. L. Décombe.—On the changes of phase produced in incident rays in the neighbourhood of total reflection, but lower than the limiting angle, by M. J. Macé de Lépinay.—Measures of wave-length in the solar spectrum; comparison with Rowland's scale, by M. Perot and C. Farry. Thirty-three lines in the solar spectrum have been compared directly with the green light of cadmium, and the wave-lengths have been plotted. The observations suggest that Rowland's scale of wave-lengths is not perfect, and indicate where corrections might be made.—On the direction of magnetisation in beds of clay transformed into hard brick by layers of lava, by MM. B. Brunhes and P. David. It is known that clay baked in a furnace acquires magnetisation in the direction of the terrestrial magnetic field at the time when it is transformed into the condition of brick. The authors have examined some beds of hardened clay covered with lava near Clermont, in the Auvergne district, with the idea of finding the magnetic condition. It appears that in general the magnetic condition of the beds is decidedly different from that of the neighbourhood, and the difference is taken to indicate the change which has occurred since the epoch when the clay was baked by the lava flow.—Thermal study of potassium hydrates, by M. de Forcrand. The observations indicate that in addition to the two compounds KOH and $KOH + 2H_2O$ there are two other intermediate hydrates, viz. $KOH + 0{\cdot}5H_2O$ and $KOH + H_2O$.—On some derived phenyl ether compounds, by M. P. Brenans. The author describes some ether-oxides and ether salts of diiodophenol and triiodophenol.—Action of pyridine bases on tetra-chloro-benzo-quinones, by M. Henri Imbert.—New reactions with *c*-butyrylacetylacetate of methyl, by M. A. Haller.—On pyromucic and isopyromucic acids, by M. Chavanne.—Contribution to the study of ortho-xylene bichloride, by M. L. Ferrand.—Precautions to be taken in the study of parthenogenesis in sea-urchins, by M. C. Viguier.—Germination of the spores of Pencillium in humid air, by M. P. Lesage.—Formation of layers of ice, in summer, in the volcanoes of Auvergne, by M. P. Glangeaud.—Action of currents of high frequency and tension on urinary secretion, by MM. Denoyés, Martes and Rouvière.—Observations of a meteor at Floirac (Gironde) on July 5, by M. E. Esclangon.—On the action of the electric current on microbes, by MM. Apostoli and Laquerrière.

SPECULATIVE BIOLOGY.

Les Problèmes de la Vie. Essai d'une interprétation scientifique de phénomènes vitaux. I[e] Partie. *La Substance Vivante et la cytodiérèse.* By Dr. Ermanno Giglio-Tos, of the University of Turin. Pp. viii + 286. Thirty-three figures. (Turin: Chez l'auteur, Palais Carignano, 1900.) Price, 10 francs.

At a time when many, if not most, biologists are confessing that they find no helpful analogy between the operations of not-living matter and the adaptive and coordinating activities of the living organism, it is interesting to find one who maintains that vital phenomena are much simpler than they seem. It is maintained in the book before us that we have invested with a veil of mystery what are really "the natural consequences of chemical, physical and mechanical phenomena." This has been a frequently recurrent idea in the history of biology; but the author has worked it out in a theoretical system in which biomolecules and biomores, bioplasm and biomonads play a part supposed to be comparable to that of atoms and molecules and radicals in chemistry.

The fundamental facts of life with which Dr. Giglio-Tos begins his materialistic reconstruction of biology are assimilation and reproduction. In assimilation, the organism adds to its own organisation at the expense of material different from itself; in reproduction, it gives rise to other units which are actually or potentially like itself. These processes of growth and multiplication may seem simple in words, but whenever we pass to the things themselves they impress us as marvellous, even in simple creatures like amœba or diatom, monad or microbe, coccidian or myxomycete. And the impression of marvellous complexity, in spite of apparent simplicity, is heightened whenever the organisms show, as they so often do, some evidence of "behaviour" (whether it be chemotactic attraction and repulsion or adaptive and coordinated movements in search of food). But by dwelling on this "behaviour," which seemed to us of the very essence of life, we have become blind—so this book suggests—to the real simplicity of the assimilative and reproductive processes, which are "truly and exclusively chemical." To prove this last statement directly is not at present possible, for we do not know the chemical composition of living matter; but what the author proposes is the legitimate and practicable test—Are the interpretative formulæ of the chemist sufficient for a simpler re-description of vital phenomena? His answer is an emphatic affirmative. To be convinced, we are invited to make a simple experiment, in regard to which a chemist's opinion would be of much interest. We are told to "feed" two molecules of acetic acid with perchloride of phosphorus; and the resulting chloride of acetyl with zinc-ethyl; we are asked to subject the resulting methyl-ethyl-ketone to oxidation; and the result is that from two molecules of acetic acid we get four.

"May we not say that the two molecules of acetic acid have assimilated and reproduced? . . . Reproduction is the fission of a living molecule ('biomolecule'), which, after a series of assimilatory reactions, divides into other molecules of the original constitution."

We do not ourselves find any cogent evidence to show that a living molecule or biomolecule exists, or that it is needed as a theoretical postulate in biological interpretation; it seems to us highly probable that living matter is a complex mixture (organisation or synthesis) of organic substances whose virtue is in their interrelations; we do not see in the acetic acid story more than an analogy of very doubtful suggestiveness. But we must let the author tell his own tale. He devotes his second chapter to mapping out the possible developmental cycles of the imaginary biomolecule. Through phases of assimilation, followed by rearrangement of atoms, the biomolecule matures and multiplies, and there are three possible schemes: of (I.) autogenetic, (II.) homogenetic and (III.) heterogenetic development:—

(I.) a becomes b, then c . . . . d . . . . m, which divides into $a+a$.

(II.) a' . . . . b' . . . . c' . . . . d' . . . . $m'=e'+e'$ (and e' may thereafter give rise to $a'+a'$).

(III.) a'' . . . . b'' . . . c'' . . . . d'' . . . . $m''=e''+i''$ (of which e'', called genetic, may regenerate a'', while i'', called somatic, cannot).

The third chapter, dealing with the physiology of the biomolecule, discusses at some length the proposition that "respiration is not a process of combustion but of oxidation," and that the formation of CO_2 is an indirect result, comparable to what occurs when acetic acid acts on isocyanate of ethyl. The author is under a misapprehension when he says that "respiration is generally regarded to-day as a simple combustion . . . . an interpretation accepted by almost all biologists." Although we cannot explain *how* the oxygen, as Pflüger said, helps to wind up the vital clock, although we cannot as yet trace the oxygen through its sojourn in the tissues, we have left the false simplicity of the crude combustion theory far behind. In the pages of the book devoted to this subject, and in those dealing with the formation of starch in vegetable cells, the author argues against positions long since abandoned, and makes no new contribution to the problems.

The fourth chapter introduces us to "the biomore," an old acquaintance with a fresh alias, the visible living particle. It is, of course, formed of biomolecules, probably different from one another and juxtaposed like the inorganic molecules in double salts. The life of the biomore is not dependent on its constitution; it lives because it is formed of molecules themselves alive. Nevertheless, the accomplishment of vital functions is facilitated by the juxtaposition of the biomolecules, and by the increase in their instability which thus results. The arrangement of the biomolecules in the biomore depending on their chemical constitution, there is in the biomore, during assimilation, a continual displacement of biomolecules by reason of their chemical changes. Physiologically considered, "the biomore is a veritable mutual symbiosis of biomolecules." Had the author developed the fruitful idea of "symbiosis," he might have been led to the conception of "protoplasm" (=bioplasm) as an organisation of substances not in themselves living, but in virtue of their interrelations giving rise to the phenomena of life.

The next chapter deals with bioplasm and the biomonad—to wit, protoplasm and the cell—another instance of the craze for rechristening. Perhaps a micrococcus or some similar microbe is composed of but one biomore, but such simplicity is rare. Most unicellular organisms consist of diverse biomores living symbiotically in an interbiomoric fluid (water, nutritive substances in solution and products of secretion). The author explains that *bioplasm* includes nucleoplasm as well as cytoplasm, and that it excludes the metaplasm; it is Huxley's protoplasm, in fact. The *biomonad* is a living unity, a symbiotic system of biomores, characterised by the chemical nature of the biomores which form the nucleus; it is a cell, in fact. But while the author emphasises the fact of symbiosis, he does not, as we have said, really appreciate the idea that vitality is an expression of the interrelations of diverse complex substances associated in a particular organisation or synthesis.

"The faculty of living resides in the biomolecules themselves. The biomores are living because they are composed of biomolecules. The bioplasm is living because it is composed of biomores. The cell is living because it consists of bioplasm. . . . The phenomena of life and their possibility are based on the properties of carbon compounds. . . . The essential characteristic of life, reproduction, is fundamentally a phenomenon of molecular fission into two or more equal molecules."

Thus assertion follows assertion, all, to our thinking, "in the air."

The author's interpretation of cell-division, which is the subject of the three final chapters of this volume, may be inferred from what has been already noticed in regard to the process by which four molecules of acetic acid may be produced from two. Assimilation is the indispensable, though not always sufficient, cause of the division; it leads to an orientation of atoms which makes a division of the biomolecule imperative; the division of the biomolecules provokes the division of the biomore, and the division of the biomores provokes the division of the biomonad. How this speculation in any way interprets the actual processes of cell-division we entirely fail to see; but we are not surprised to find the author insisting that the phenomenon of division is independent of the nature of the division-figures. The figures cannot be chemically interpreted, so they do not count for much. They are dependent on the initial disposition of the biomores in the biomonad.

Assimilation leads to doubling of biomolecules, and this to doubling of biomores; the doubling expresses itself as cell-division, because of the particular orientation of the component biomores, which in turn is due to their reciprocal attractions. If this be granted, it is possible to deduce a number of "rational laws of cell-division," which may be verified by observation. The author deduces no fewer than twenty-eight laws, but many of them read more like assertions, while others are certainly not deductions, but statements of observed fact. We must content ourselves with referring to the first three. The first law is that the living parts of the cell have all the same importance in cell-division; the biomores enjoy perfect equality; this is "a natural consequence of the previous interpretation," and, like it, is all in the air.

The second law is "that the divisions of the diverse parts of the cell are independent of one another," and the third "that the direction of the division of the nucleus is determined by the direction of the division of the cytoplasm." This may seem to the matter-of-fact a contradiction, but the author maintains "that between the cellular body and the nucleus there is at once a complete independence and a close dependence." This is too subtle for our understanding.

Recognising that the phenomena of cell-division, which he has interpreted as "purely and exclusively mechanical," were somewhat "ideal" ("sont naturellement quelque peu idéaux"), the author proceeds to discuss the modifications which the ideal scheme suffers in real life. Perhaps this may prove to be the most useful part of the book, for the author proposes a series of thirteen problems dealing with the influence of the position of the central corpuscles, of gravity, of mechanical obstacles, of pressure, of the cell-membrane, of adjacent cells, and so on (pp. 184–285). We do not propose to discuss these problems, for an appreciation of the author's mode of treatment is quite impossible to those who find themselves compelled to reject his premises. But let us state his general conclusions.

The property of dividing, which characterises living matter, is not due to a special force. It is a consequence of the constitution of living matter and of assimilation, which doubles the number of the parts of the system and may thus lead to the formation of two systems. The force which unites the parts of living substance in a system is the same as that which unites the parts of dead matter. This force is sufficient to explain the phenomena of division. The figures which characterise cell-division are the structural results of the constitution of living matter, and have no importance in the phenomenon, which is purely and exclusively mechanical. As to the direction of the division, it is partly determined by the position of the central corpuscles, but almost wholly by environmental influences in the widest sense.

Let us sum up our impression of this ambitious book. The author abstracts from his consideration of the living organism its most characteristic features of adaptive and coordinated behaviour, and thus gives a false simplicity to the whole problem. He invents a theoretical system of biomolecules, biomores, bioplasm and biomonads, which depends on the postulate that there are biomolecules—a gratuitous assumption, since it is quite as likely that matter exhibiting vital phenomena owes its virtue to the interrelations of a peculiar organisation or synthesis of not-living molecules. From the doubling of a chemical molecule (of acetic acid) he passes, with an entirely inadequate discussion of the magnitude of the step, to the structural division of a cell. In spite of his hypothetical diagrams, his mathematical formulæ and his twenty-eight so-called laws of cell-division, he leaves the problem all unsolved. The use of a hypothetical system is to furnish convenient modes of re-statement in simpler terms, but we cannot find that the system of Dr. Giglio-Tos makes the division of the amœba under our microscope any more interpretable than it was before. The author is continually combating the assumption of "special forces"—and here we are at one with him—but the neo-vitalists do not believe in vital force. They content themselves with disbelieving that the behaviour of a living organism is as yet interpretable in terms of the formulæ used by the chemist and the physicist. And we find nothing in this volume to shake this disbelief.

J. A. T.

A PHILOSOPHER ON EVOLUTION.

The Limits of Evolution. By Prof. Howison. Pp. xxvii + 380. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1901.) Price 7*s.* 6*d.* net.

THE main argument of the book is clearly summarised in the preface. Nothing has any real existence except mind. There are a number of coexistent minds. All else is but the items of their experience, which they arrange in order for themselves. God is the "fulfilled type of every mind," an ideal to which it is trying to assimilate itself. These minds are citizens of an eternal republic. They have had no origin in time. They have not been created in the sense in which the word is ordinarily understood. They are free: "nothing but their own light and conviction determines their action towards each other and towards God." This freedom is made possible by the substitution of a final for an efficient cause. "Real creation means such an eternal dependence of other souls upon God that the non-existence of God would involve the non-existence of all souls." Evolution is the "movement of things changeable towards the goal of a common ideal," and spirits can "neither be the product of evolution nor in any way subject to evolution," which can only reign in "the incomplete and tentative world of experience."

The first and last essays elaborate the theory, insisting always on the freedom of the will. It is in order to prove that the will is free that our author has established his republic of independent minds. If the mind of an individual man is merely part of the force that permeates the whole universe, it can have no freedom. Pantheism, therefore, must be rejected. Creation, too, in the old sense must be given up; if created, the mind can have no independence. Hence the assumption that it has had no beginning and will have no end. Thus war is declared against the monistic philosophy, according to which body and mind are but different aspects of what is divisible only in thought, and the mind, therefore, as perishable as the body.

Prof. Howison fears that philosophy is tending towards determinism, and this tendency he considers fraught with the gravest danger. No doubt if a man puts his determinism into practice, and, when called upon to act, feels that he is a mere automaton set in motion by influences from without, he is not one who can fill any post where energy and determination are required. We must imagine that our wills are free or we are helpless. Whether we are really free is unimportant. The belief is strong in almost every man, at any rate in almost every European. Most men are content to leave the matter undiscussed, holding that they have a real freedom, however inexplicable and even unthinkable it may be. But Prof. Howison tries to find a philosophic explanation for the belief, and, interesting as his book is, we cannot think that he has been successful.

Let us first consider his "republic of minds." They exist in a world the existence of which is "incomplete and tentative." Nothing but mind is really existent. We start, then, each of us with our own mind. And how do we become cognisant of the existence of other minds? This can only be through our bodily senses. Yet our bodies are not things really existent. Moreover, we cannot touch, see or hear other men's minds; we only infer their existence from their looking out upon us through their bodily eyes or speaking to us with their bodily vocal organs. Thus the existence of a real world of minds is accepted on the evidence that is obtained for us by mere phenomena. Next as to the free will that Prof. Howison has to offer us. If he reduced the whole universe to unreality except each man's own *ego*, then the mind would move *in vacuo*, not tyrannised over by any external influences. As he himself puts it, the condition of freedom for man is that "the world shall be a world of *phenomena*—states of his own conscious being, organised by his spontaneous conscious life—and not a world of 'things-in-themselves.'" But he does not make other minds mere phenomena.

Any individual mind must, therefore, be influenced from without by the other citizens of the republic of minds. No doubt even under these conditions there may be autonomy: the mind may decide *in accordance with its own character* which influence from without it will allow to prevail with it. The existence of other minds need not destroy autonomy in this sense. But free will, such as this, is quite consistent with the monism which Prof. Howison condemns. It is not the freedom in which the ordinary healthy man has at least a practical belief. He has the feeling that he can transcend his own nature, conquer his weaknesses and bad tendencies and develop other and better tendencies. It may be impossible to explain how he can have such a power. Certainly this book leaves us dependent on our instinctive feeling of freedom.

Next as to our author's view of evolution. Evolution, he insists, cannot explain the origin of life or the origin of mind. But no clear-headed evolutionist holds that evolution can originate. We must assume an underlying force which, through evolution, is variously manipulated and concentrated. As to the ultimate origin of the underlying force, evolution has nothing to say. This much we may concede. But Prof. Howison assumes that, not only mind, but *the individual mind* has existed from eternity, and in this he is unreasonable. The development of certain bodily organs proceeds *pari passu* with the development of mental power. We can trace the gradual evolution of nerve till it culminates in the human brain. We are bound to assume, then, that a particular mind is the product of evolution; like the body, it has been elaborated out of something that preceded evolution. This question is not fairly faced by Prof. Howison. In a footnote (p. 10) he allows that we can trace the upward steps of intellectual development, and there he leaves the matter, assuming as the basis of his dualistic philosophy that the mind of each individual has existed from eternity and has, apparently, been inserted extranaturally in the body.

Some of the contradictions involved in his system our author sees and attempts to remove. If each individual mind has an independent existence from eternity, monotheism seems to disappear. On the other hand, if monotheism is insisted on, what becomes of the free-willing, independent minds, the citizens of the republic of minds? We are expected somehow to accept what look like contradictory propositions simultaneously. Again, all minds are different from one another and yet all are straining towards the same ideal. Here is a sentence that aims at explaining this:—

"In fine, its self-definition (*i.e.* the self-definition of each spirit) is at the same stroke in terms of its own peculiarity, its own inerasable and unrepeatable *particularity*, and of the supplemental individualities of a whole world of others—like it in this possession of indestructible difference, but also like it in self-supplementation by all the rest: and thus it intrinsically has *universality*" (p. 353).

We have left little space for the discussion of the essays that deal less directly with the main argument. One of them gives an interesting account of later German philosophy, another deals with the "art-principle in poetry." The essay on the "Right relation of reason to religion" is certainly the best. Everywhere in the book, but most of all in the last-mentioned essay, we feel that the author is a man who hates any notion that is in itself or in its implications degrading to human nature. In religion he boldly rejects authority and bases it on reason, defined as the mind's own insight, as its true source.

There is much in the book that it is good to read. The author hates pessimism; most of all he hates determinism as a belief that unnerves the character and robs human life of what is best in it. But he has found no philosophic basis for his views. In fact, we have in this book an instance of what is not uncommon: a man's opinion is often of far greater value than all the reasons he is able to give for it.

COAL MINING.

A Text-Book of Coal-Mining. By Herbert W. Hughes. 4th edition. Pp. 513: 670 figures. (London: Griffin and Co., Ltd., 1901.) Price 24*s.* net.

MR. HUGHES and his publishers may fairly be congratulated on the success of a text-book which requires a new edition about once in every three years, and this, too, in spite of its high price, which is beyond the means of the average student. The new edition contains ninety more pages and 184 more illustrations than the first.

It can hardly be expected that a large treatise of this description should be free from some minor errors; but when these are decidedly numerous, one cannot help feeling that there is want of care on the part of the author. Mr. Hughes seems to think (p. 3) that reversed faults are rare; surely he can never have carefully looked at the sections of some of the Continental coalfields. On p. 4, while speaking of the Carboniferous system in Scotland, he appears to be ignorant of the coal in the Calciferous Sandstone below the Carboniferous Limestone.

The chapter on boring is weak; it may be said with a good show of truth that the colliery engineer nowadays frequently entrusts the work of boring to a contractor; but this is an argument for omitting the chapter altogether, rather than for treating the subject in a slovenly fashion. There is no figure of a derrick of any kind. On p. 22 it is stated that the American boring tool is rotated by hand; this was done formerly, nowadays turning by hand has been given up. The rotatory and percussive systems of boring are mixed up in a manner puzzling to the student, for the description of the diamond drill says: "This method differs from the others in the fact that the tool receives a rotary instead of a percussive motion"; and yet just above, on the very same page, Mr. Hughes has been describing Davis's calyx drill, which works by rotation.

Timbering is not treated so fully as one would like, and we scarcely think that Haselmann would be content to hear his process of preserving timber spoken of as similar to the Aitken process.

An author should be consistent. In speaking of the transmission of power (p. 46), it is said that the choice is limited to compressed air and electricity, and yet a little further on we have a description of Brandt's drill, which is driven by water.

Mr. Hughes is wrong in supposing that the "straw" cannot be employed for igniting charges of explosives other than gunpowder. He is a little behind the times with regard to water injection while boring, as he makes no mention of Bornet's system, which is an unquestionable improvement upon the method tried at Blanzy in 1889, and not 1899.

Granted that some knowledge of electricity on the part of the mining engineer is nowadays desirable, if not imperative, is it not better that he should obtain the rudiments of that knowledge first-hand from an electrician rather than second-hand from a miner? Why should the writer of a mining text-book think it his business to explain the electrical units? Mr. Hughes evidently expects the student to learn elsewhere what is meant by such terms as "limestone," "sandstone," "horse-power," "symbol," "molecular weight"; why then does he go out of his way in the case of electricity, upon which subject there is ample published information? As a consequence, we find the mistake of defining the ampere as "the quantity per minute."

In the same way, it would be better to leave the question of generation of power to an expert. Steam-boilers are mentioned in a somewhat cursory fashion, and all other modes of generating power ignored. One of the statutory fittings to the boiler, viz. the safety valve, is described, but the other two, the water gauge and the steam pressure gauge, are not noticed.

On page 432, Mr. Hughes revives the old question whether the introduction of safety lamps will not produce an increase in the number of deaths from falls of roof and side. Statistics have shown that this fear is ungrounded, and it is a pity to throw doubts upon the subject.

While calling attention to the existence of very numerous minor defects, one cannot be blind to the useful work which Mr. Hughes has done in compiling what is unquestionably the best text-book on coal-mining in the English language, and for keeping it up to date. For this he well deserves the thanks of students and mining engineers. Plate II., reproduced from Mr. Hughes' own photographs, is excellent.

OUR BOOK SHELF.

The Human Nature Club. By E. L. Thorndike. Pp. viii + 235. (London: Longmans, 1901.)

Psychology of Reasoning. By Alfred Binet. Pp. 188. No. 47 of the "Religion of Science Library." (London: Kegan Paul, 1901.)

MR. THORNDIKE, already favourably known by his ingenious experimental studies of animal intelligence, has achieved a very fair measure of success in the bold attempt to compose an easy introduction to psychology in dialogue form. His little work is bright and interesting, and should be found an excellent introduction to the genetic study of mental processes. In particular, it is well adapted to be taken up as a first course preliminary to the study of Prof. James' great "Principles of Psychology." In some respects Mr. Thorndike, perhaps, defers too much to the authority of his eminent countryman. When his book reaches a second edition he might do well to add to the chapter in which Prof. James' well-known theory of the emotions is expounded some indication of the grave difficulties which beset the theory, and the flaws of the reasoning by which it is supported. Perhaps, too, he will see reason to modify the passage in which he repeats certain weak metaphysical arguments of the professor in favour of the immortality of the soul. Mr. Thorndike's one really weak point is his style. Dialogue, to be successful, should never be a direct imitation of actual speech, still less of a type of speech like that of Mr. Thorndike's characters, which is at once undignified, ungraceful, and occasionally gravely inaccurate, as, *e.g.*, when the brain is spoken of as "just a 'lot' of nerve-cells," an expression as unfortunate as it is inelegant.

The translation of M. Binet's interesting little work, which appears identical with one issued by the same publishers in 1899, is still valuable as a repertory of interesting experimental facts as to the pathology of the perceptive and reasoning processes. It should, however, be clearly understood that the general psychological basis adopted by the author consists of doctrines which are now largely antiquated. The doctrine that "ideas" are "revived sensations," and that perception and reasoning are founded upon "association," may now be regarded as practically dead, while the part played in mental life by "fusion" needs to be stated with more accuracy than is shown by M. Binet. And the whole attempt to state the relation between the subject and predicate of a judgment, or the premisses and conclusion of an inference in terms of association, seems to rest upon the common but disastrous confusion of psychology—the study of mental processes—with logic, the study of the laws of evidence.

A. E. T.

Outlines of Physiography. An Introduction to the Study of the Earth. By A. J. Herbertson, Ph.D. Pp. viii + 312. (London: Edwin Arnold, 1901.) Price 4*s.* 6*d.*

WERE it not for the statement at the head of Chapter xxvi., we should not have imagined that this book was intended for the use of students preparing for the South Kensington examination, the ground covered being what is generally regarded as elementary physical geography. The experimental portions of the syllabus, dealing with the physical and chemical properties of matter, are entirely omitted, while other subjects are introduced. Nevertheless, the table of contents indicates a carefully considered classification of the various points to be dealt with, which might have formed the basis of a very profitable course of reading. The subsequent treatment, however, is generally so sketchy that the result will probably be the communication of a number of facts to the reader rather than the enlargement of his powers of observation. A certain amount of carelessness is noticeable in the part which discusses the relation of the earth to the other heavenly bodies. Thus, in Fig. 12, the sun's meridian altitude on March 21 is marked 45°, although there is no reference to the latitude of the place of observation; on p. 31 it is stated that eclipses only occur when the planes of the orbits of the earth and moon coincide; and on p. 34 the obliquity of the ecliptic is not included in the causes affecting the equation of time. The author is much happier in his descriptions of the physical features of the earth and of the causes which mould them, and some of the chapters in this part provide an interesting introduction to various branches of earth-knowledge.

The illustrations are both numerous and good, but the frequent absence of direct references in the text considerably reduces the value of many of them.

Bird Watching. By Edmund Selous. Pp. 337. The Haddon Hall Library. (London: J. M. Dent and Co., 1901.) Price 7*s.* 6*d.*

MR. SELOUS may fairly be called a pioneer. The habits of some few wild animals, such as bees and ants, which can be observed without much difficulty, have been carefully studied; but, except in rare and isolated instances, wild birds have never been made the object of prolonged and patient watching. Since the days of White, Naumann and Montagu, the energies of ornithologists have been devoted rather to problems of classification and distribution than to the "life and conversation" of the birds, and though books by field-naturalists (real and so-called) have been legion, few of them have thrown much light upon problems of animal life and intelligence. Curiosities of bird-life are constantly reported, but the every-day habits of common birds have not been patiently and persistently studied. This work has now been begun by Mr. Selous with admirable accuracy and self-restraint, and his book should have a most wholesome effect on our rising generation of ornithologists, who need to realise that there is a vast field of work still left for them in this country, and that it is not necessary for them to travel long distances in order to make themselves useful or famous.

It is, of course, no easy matter to watch carefully such nervous and restless creatures as birds; a real observer must have both leisure and patience, and must be duly qualified, or train himself to become so, in many other ways. Readers of the *Zoologist* are well aware that Mr. Selous has the necessary qualifications in a high degree, and can have no doubt as to his absolute trustworthiness; and this is everything in a book which is sure to be used by biologists as material for speculation. He has made his notes, for the most part, on the spot, as he watched; where he writes from recollection he is careful to tell us so, and even there we feel that the image left on his mind is clear and strong, just because he sees everything while watching with such an intensity of interest. The notes taken on the spot are often printed *in extenso*, as they were also in the *Zoologist*, and constitute the most valuable part of the book, and it may be hoped that *all* the notes of this kind that he has made may be carefully preserved, whether published or not. But Mr. Selous not unfrequently makes suggestions by way of explaining the phenomena he has observed, and these are always useful and interesting; they are put out tentatively, and the book affords abundant evidence that he does not allow himself to jump at conclusions.

Without anticipating the pleasure or profit which ornithologists and others are sure to gain from the book, it may be said here that Mr. Selous has watched birds courting, dancing, nest-building, feeding, flocking, climbing, singing; and that the range of his studies extends from large birds such as the great skua, the great plover and the cormorants, to the sparrows, chaffinches and blackbirds of our gardens and rickyards. There is a good index, which greatly increases the working value of the volume.

LETTER TO THE EDITOR.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

History as a Science.

THERE have lately appeared in NATURE suggestive summaries of addresses by Sir H. Roscoe, Dr. D. J. Hill and Prof. Ramsay on, respectively, "The Work of the London University," "The Extension of Knowledge" and "The Functions of a University," together with various other papers of an educational character. And to these I would beg permission to add some remarks on the importance of the recognition and endowment, in this country also, of history as a science. Three things are required to make of a body of knowledge a science: (1) verifiability of statements; (2) sufficient length and breadth of survey to make possible the discovery of laws, or verifiable generalisations; and (3) the actual discovery, or an approximation to the discovery, of one or more laws of the facts constituting the body of knowledge considered. But history, as it is commonly studied and taught in British Universities, embraces such brief periods that it can, at best, be characterised only by the most elementary of these three requirements. In geology we have had a science of earth's history since the discovery of the law of the succession of strata. In anthropology we have not, as yet, a science of man's history, seeing that the law of the succession of civilisations has not yet been discovered, or has not, at least, yet been adequately verified. The first object, however, of this letter is briefly to point out that, though the science of man's history would be the most complex of the sciences of evolution, yet the immensely varied results of the researches of the last half, and particularly of the last quarter, of the nineteenth century do bring within the scope of reasonable aims the discovery and verification of general laws of history, with all the incalculable consequences which would therefrom follow in the power given to interpret the past, to guide the present and to forecast the future. And the further object of this letter is to urge that, endowed as the study of history as a science is in all the greater Universities, both of Europe and of America, it should at length be adequately endowed also in British Universities, and more especially in those of Scotland, now so munificently endowed, and whose sons, since Adam Smith, in his "Wealth of Nations," David Hume, in his "Natural History of Religion," and John Millar, in his "Origin of Ranks," have been among the foremost workers and discoverers in this *Scientia Scientiarum*.

But theories of history have also their history. And we may better appreciate the argument for the endowment, at length, of chairs of general history—of history studied with such generality as to make possible the discovery of laws, or, in a word, of history as a science—if we cast a glance on the history of general studies of history during the last century and a half. We shall find it clearly divisible into three periods, on the third of which we are now entering. In all these periods, indeed, two great directions, or rather two great methods of historical research, may be noted—the one synthetic and speculative, the other analytic and inductive. But of the former character was more distinctively the method of the first period, of the latter character the method of the second period, and again, but with incomparably more justification, considering the enormous wealth of facts accumulated in the second period, the third period promises to be, while distinctively synthetic, verifiable in its syntheses.

The first period may be dated from Turgot's second discourse at the Sorbonne, "Sur les Progrès successifs de l'Esprit Humain" (1750), and especially from Hume's "Dialogues on Natural Religion," written about the same time, and his later-written "Natural History of Religion" (1757). This synthetic and speculative era culminated in the philosophies of Hegel and of Comte—for Comte's philosophy is entitled to be called "positive" rather because of its speculative dogmatism than of its inductive verifiability. And around these giants of the forest there grew up such a luxuriance of minor "philosophies of history" as produced a reaction against all general views of history—a reaction from which we, in Great Britain, have unfortunately been the latest to recover.

But among Hume's contemporaries and friends were two masters of the other mode of historical research—the analytic and inductive—Adam Smith and John Millar. From their time to ours the drudging brother has conducted his researches side by side with the high-flying brother, each too apt to sneer at the other, though the function of each was indispensable for the success of the great quest consciously or unconsciously common to both. To the aid of inductive rather than of speculative historical research came, after 1859, the "Origin of Species" year—the immense development of the general theory of evolution which added to the theory of kosmological evolution suggested by Kant and Laplace the theory of biological evolution elaborated by Darwin and Wallace. Simultaneously with the development of this more complex theory of evolution, the researches into man's psychical as well as physical history have had the most fruitful results. And these are now being more and more clearly seen to be contributions to a theory of anthropological evolution which will transform unverifiable, or but partially verifiable, "philosophies of history" into a science of history, conceived at length as the most complex of the verifiable evolutional sciences.

The chief, perhaps, of the contributions to such a science of history may be thus briefly summarised. (1) The ethnological discoveries, which have resulted in a theory of the origins of civilisation in a conflict of higher and lower races. (2) The folklorist discoveries, generalised in a theory of primitive conceptions of nature as conceptions of its solidarity through the interaction and limitless transformation of its parts. (3) The logical and psychological discoveries, which have verified the "Secret of Hegel," or the theory of the process of thought, both individual and historical, as an advance through differentiation to a higher integration. (4) The physical discoveries generalised in the principle of the conservation of energy, and hence in a theory of scientific conceptions of nature as still, even as primitively, conceptions of its solidarity through the interaction of its parts, but now with the profoundly important substitution of the notion of *proved* equivalent, for *supposed* limitless transformation. And (5) the historical discoveries resulting in a theory of civilisation as a process with dateable (as yet no doubt only approximately dateable) beginnings under definable conditions; as a process the astonishing unity of which becomes more and more apparent with the progress of the researches which have demonstrated the derivation, certainly, of Semitic, and, almost certainly, of Chinese, from Chaldean civilisation; the later derivation of Aryan, through Pelasgian, from the connected Chaldean and Egyptian civilisations; and the derivation possibly (as I personally venture to think probably) of the civilisations also of the New from certain of those of the Old World; and, finally, as a process the unity of which further appears in such correlations and synchronisms of development as that illustrated, for instance, in what I have called the moral revolution of the sixth (or fifth-sixth) century B.C., in all the countries of civilisation from the Hoangho to the Tiber, and which has been more and more fully verified since I pointed it out in 1873 ("The New Philosophy of History"). The other theories I have referred to may, or may not, be found fully verifiable. But surely it may reasonably be anticipated that, from consideration of the ever-accumulating facts of these five great classes, we shall sooner or later discover general laws of history—laws of racial evolution, of intellectual development and of social progress—and draw from them results of the highest possible importance for the interpretation of the past, the guidance of the present, and the forecasting of the future?

But, if so, and if I have thus succeeded in showing that the discovery and verification of general laws of history is now brought within the scope of reasonable aims, it should be unnecessary for me to waste many words on the more practical object of this letter, viz. to urge that, endowed as the study of history as a science is in all the greater Universities of our European and American rivals, it should at length be adequately endowed also in the Universities of England, and more especially, perhaps, of Scotland. For, as Lord Rosebery has over and over again said—for instance, the other day (May 15) at a meeting of the University of London—"The struggle of this coming century will not be one so much of brute force as of trained intelligence. . . . No nations are satisfied with the standard of education that prevailed twenty-five years ago. Every nation demands a more keen and more trained and, if I may use the adjective, a more versatile intelligence than that which was adequate for the business methods of the Empire in former days. In other words, we have to meet much keener competition in every department of life. And I hope, though perhaps not with much confidence, that all our educational institutions are recognising that fact and preparing to furbish up their somewhat antiquated methods to meet the demands of modern civilisation and modern competition." And at the same meeting the Vice-Chancellor, Sir Henry Roscoe, said, "If we are to meet successfully the constant changes of thought and manner of life to which a highly-organised society is increasingly liable, our Universities must not be content with giving instruction or testing attainment, however high, but must make real contribution to the knowledge which alone, in some form or other, will be a guarantee of the stability of that society."

I shall only add that the endowment and teaching of history as a science, the most complex of the sciences of evolution, should renew and vivify the teaching of all other sciences. For as the sciences of evolution, the metamorphic sciences as I would call them, are founded on the physical sciences, the ethical sciences are founded on the metamorphic sciences, and especially on that highest and most complex of all these sciences, the science of history, or science of anthropological evolution. More particularly within the scope of the more general or anthropological professorships of history it would come to set forth in their due connection, and in the inferences to be drawn from them, the great, yet hitherto, in this country, hardly known and wholly unappreciated, results of modern research with respect to the origin and history of civilisation. From such chairs also the keynote would be struck which would give a cooperating harmony to the work of every minor chair in the great faculty of history. For a general theory of civilisation, a theory aiming at setting forth the laws of man's history, would touch the whole circle of historical studies. Every special chair, therefore, of the faculty of history would be a centre of fruitful scientific criticism of whatever theory might be put forth from the chair of general history or sociology (if such should be its title). Imagine the result in new knowledge of such an interworking of generalising theory and verifying research! Were the faculties of our Universities, or even of one of them, reorganised as the contemporary development of the idea of evolution demands, what a school of cooperating workers would thus be created! From standing lowest among the great Powers in organisation and encouragement of intellectual work, Great Britain would take her place as highest! "Lords and Gentlemen of England! consider what nation it is whereof ye are, and whereof ye are the governors, a nation not slow and dull, but of a quick, ingenious and piercing spirit; acute to invent, subtle and sinewy to discourse, not beneath the reach of any point the highest that human capacity can soar to." And what lacks there in order to our showing ourselves worthy of this noble adjuration of Milton's but such institutions as our Universities might be if organised, not as I suggest, but as the idea of evolution demands? J. S. Stuart-Glennie.

THE CONGRESS ON TUBERCULOSIS.

The most sanguine expectations of those who have been responsible for the organisation of the British Congress on Tuberculosis could scarcely have led them to anticipate that such a remarkable success would attend their efforts as that which has been achieved. The work of some of these congresses appeals almost entirely to experts, whilst that of others has its interest only for the popular mind. Where, however, such a question as tuberculosis is concerned, the interests involved are so great and far-reaching that the medical man, the dabbler in science and the man in the street are all alike interested and fascinated. From Prof. Koch's splendid address, delivered on the first working day of the Congress, to the practical closing resolutions submitted to the Congress on Friday, those who attended would be ill to please did they not consider themselves provided with subjects for most interesting discussion.

One of the most important items in the success of the Congress was Prof. Koch's address, in which, in masterly fashion, he enumerated the various steps to be taken for the gradual elimination of tubercular process. The very fact that he resiled from one of his original positions—that bovine and human tubercle bacilli are practically identical—aroused such interest that, had no other single subject been discussed, the success of the congress would have been assured, and Prof. Koch is to be congratulated on raising a subject of such vital importance. It cannot but be felt, however, that the experimental evidence on which his opinion is founded is scarcely sufficient to warrant such a sweeping generalisation as that put forward; whilst the clinical evidence brought forward is even less convincing.

The experimental evidence can only be allowed to stand or be controverted on the production of positive evidence that bovine tuberculosis is communicable to man. Such evidence was at once forthcoming, Dr. Ravenel of Philadelphia bringing forward three cases of such infection that had come under his personal observation; one of the patients died, whilst in one more at least the bovine tubercle bacillus was recovered from the local lesion. These cases are, of course, of very great importance, and now that doubt has been thrown on the possibility of such infection, a most careful outlook will, in future, be kept for similar cases. From the clinical side, Prof. Koch's evidence is not convincing, especially as he maintains that no tubercular lesion can be accepted as arising in connection with the intestinal canal in which some effect is not produced on the mucous membrane. It appears to be the experience of pathologists who have examined a large number of cases of abdominal tuberculosis (tabes mesenterica) that a certain proportion, at any rate, whilst showing no local lesions such as ulceration or swelling of the mucous membrane itself, give abundant evidence of invasion of the mesenteric glands, and in a certain proportion of these cases the mesenteric glands only are affected, this proportion ranging from 14 per cent. (Woodhead) to 28 or 29 per cent. (Shennan and Still). Such affection of the lymphatic glands can scarcely be explained on any other assumption than that the infection has taken place from the alimentary canal, whilst there seems to be further collateral evidence that, in some of these cases at any rate, the infective material has been introduced through the agency of cow's milk. So strong is this evidence that most pathologists, on this ground alone, appear to have considerable hesitation in accepting Koch's statements without very careful corroboration, and it is to be hoped that in England, as in Germany and America, the matter will be put to the test as soon as possible. It should be mentioned that Prof. Virchow, one of the greatest authorities on tubercle, is by no means satisfied of the accuracy of Koch's conclusions on this matter. Whatever may be the result of future investigations, however, Prof. Koch may be most heartily congratulated on the courage and lucidity with which he expounded his views and on the interest that he has aroused in the question by the firing off of his bombshell, as it has been called.

The following remarks made by Lord Lister after Prof. Koch's address are of especial interest:—

Lord Lister said the discourse they had listened to was full of profound interest from the beginning to the end. But what had chiefly riveted their attention had been the startling thesis that bovine tubercle could not develop in the human body. This was a matter of enormous practical importance, because, if this conclusion were sound, it would greatly simplify their preventive measures; but it would be a very serious and grievous thing if the rules now in force for securing purity of milk supply should be relaxed and it should turn out after all that the conclusion was erroneous. For his own part he thought the evidence adduced by Dr. Koch to show that human tubercle could not be communicated to bovine animals very conclusive. At the same time he agreed with him that in a matter of such great importance further inquiry was desirable. But even if that were established it would by no means necessarily follow that bovine tubercle could not be communicated to man. He took in illustration the case of variola. Attempts to inoculate human small-pox into the calf had been so very rarely successful that eminent pathologists had concluded that small-pox and cow-pox were two entirely different diseases. We now knew that this was an entire mistake; that cow-pox was small-pox modified by passing through the cow. He referred to some very instructive experiments by Dr. Monckton Copeman, who entirely failed to inoculate human small-pox into the calf, but invariably succeeded in inoculating it into the monkey, and was as invariably successful when he introduced matter from the pustules in the monkey into the calf, the result being ordinary cow-pox which could be used for vaccinating children. It may be that some species of animal may serve as an intermediary host for tubercle between man and the bovine species. Or it may turn out that, if a sufficient number of experiments are made, human tubercle may prove occasionally transmissible to the bovine animal, as small-pox is in rare instances to the calf, and that the bovine tubercle so produced may be transmissible to man, as is the virus of vaccine. The evidence, necessarily indirect, on which Koch relied as showing that bovine tubercle could not be transmitted to man did not seem at all conclusive. It consisted mainly in the alleged rarity of primary tubercular intestinal lesion in children, in spite of the multitudes of tubercle bacilli swallowed by them in milk. Even if it be admitted that primary tubercular intestinal lesions are as rare in children as Koch's statistics indicate, it is certainly true that tabes mesenterica exists in a considerable percentage of children that die of tubercular disease without tubercle being found in any other part of the body. When the mesenteric glands are thus affected without any discoverable intestinal lesion, the natural, and, indeed, inevitable, interpretation seemed to him to be that the tubercle bacilli had passed through the intestinal mucous membrane without causing obvious lesion in it, and had been arrested in the glands of the mesentery. It was known that even typhoid bacilli, whose essential place of development is the intestinal mucous membrane, occasionally pass through it without producing the characteristic lesion. And if this might occur with the typhoid bacilli, how much more likely was such an occurrence with tubercle bacilli! If this be so, Koch's main argument falls to the ground. As regards the experiments Koch had referred to of inoculating bovine animals with material from the glands of children affected with tabes mesenterica, the result being negative, these experiments had been but few; and even were they more numerous, they would not, to his mind, be quite conclusive. It might be that tubercle from milk in the intestines might be so modified by passing through the human subject that the bacilli in the mesenteric glands, though derived from a bovine animal, might be no longer those of true bovine tubercle, but bacilli having the characters of human tubercle little disposed to develop in cattle. The Congress would probably require a more searching inquiry into the subject before accepting this doctrine of the immunity of man to bovine tubercle.

In all other points Prof. Koch, Dr. Brouardel and Prof. McFadyean are thoroughly at one, and they carried with them, by the simplicity and earnestness of their statements, the whole of the members of the Congress, and the effects of their work and observations were plainly manifest in the resolutions that were submitted at the final meeting. These may be summed up in the statement that for the prevention of tuberculosis it is necessary to attend to the housing of the people, to the provision of a sufficient supply of fresh air, as good nutrition as possible, and to the prevention of the dissemination of the tubercle bacillus (for which purpose proper precautions should be taken to have it collected and destroyed as soon as it comes from the patient); for the cure of consumption fresh air, good food and well-regulated exercise; whilst in regard to bovine tuberculosis there seems to be no difference of opinion that, until the question raised by Prof. Koch is finally settled, no relaxation of the methods at our disposal for the examination and confiscation of tuberculous meat and milk should be allowed.

The work of the sections was, of course, somewhat more specialised in character. The report of the combined discussion on tuberculin will direct attention to the advantages and disadvantages claimed for and against the use of this therapeutic agent. Other methods of treatment also received full attention in Section I (Medicine).

In Section II. (Preventive Medicine) preventive measures were fully discussed, and the number of papers brought forward and dealt with give ample evidence of the interest taken in the work of this section.

In Section III. (Pathology and Bacteriology) some of the most useful work that came before the Congress was discussed. We would specially refer to Prof. Benda's paper on the channels of spread of tuberculosis and Dr. Ravenel's paper on the relation of bovine to human tuberculosis. This latter paper was exceedingly well-timed from the fact, already mentioned, that the author had to record three cases of infection of the human subject by bovine tuberculosis.

In Section IV. (Veterinary Section) an exceedingly interesting series of papers was discussed, especially one dealing with the application of tuberculin to cattle supplying milk. In connection with this, Prof. Bang pointed out that tuberculous animals might have non-tuberculous lesions of the udder; but, if there was any suspicion of tuberculosis of the udder and the animal was otherwise tuberculous, the benefit of the doubt should always be given in favour of the consumer, and the lesion should be looked upon, temporarily at any rate, as of a tubercular nature, and the necessary precautions should certainly be taken. Where, however, it could be proved that the lesion was non-tuberculous he thought that the milk might sometimes be used, if proper precautions were taken; though we should imagine that most people would consider the proper precautions in such a case would be absolute sterilisation of the milk.

As proof of the great interest taken by the King in the work of the Congress, His Majesty received a number of the foreign delegates in the Throne Room at Marlborough House. The delegates were accompanied by the Earl of Derby, Sir William Broadbent (chairman of the Organising Committee), Prof. Clifford Allbutt (regius professor at Cambridge and chairman of the General Purposes Committee), Mr. Malcolm Morris (honorary secretary-general of the Congress), and Dr. St. Clair Thompson (honorary financial secretary of the Congress). The following delegates were presented by the Earl of Derby, but Dr. Koch, who had promised to open a discussion at Eastbourne, and a few other foreign delegates were unable to be present:—Prof. Osler and Prof. Janeway, United States; Hofrath Prof. von Schrötter and Prof. Dvorak, Austria; M. le Sénateur Montefiore Lévi and Dr. van Ryn, Belgium; Dr. Mickailovsky, Bulgaria; Prof. Bang and Dr. Charles Gram, Denmark; Dr. Brouardel (Doyen de la Faculté de Médicine de Paris), Prof. Bouchard and Prof. Nocard, France; Geheimrat Prof. Gerhardt, Prof. Flügge, Geheimrat Prof. von Leyden, Prof. Fraükel, Dr. Werner and Dr. Dettweiler, Germany; Prof. Thomassen, Holland; Prof. Koranyi, Hungary; M. Malm, Norway; Prof. da Silva Amado, Portugal; Señor Don Antonio Espina y Capo, Spain; Hof-Marshal Printzjold, Sweden; and Dr. Neuman, Switzerland. His Majesty shook hands with each delegate as he was presented, and then said:—

"GENTLEMEN,—Let me express to you the great pleasure and satisfaction it has given me to ask you to come here to-day; I only regret that you should have arrived during such a severe thunderstorm. It has been a source of great concern to me that, owing to circumstances over which I had no control, I was prevented from presiding at the opening of your important Congress and attending its meetings; but I can assure you that, though not present, I take the deepest interest in its proceedings, and that I follow with much interest, through the medium of the daily Press, the papers which are read and the discussions on the subject. There is no more terrible disease than that known as consumption, and I only hope and trust that you may be the means of minimising its evil effects, and thereby receive the gratitude of the whole world. There is still one other terrible disease which has up till now baffled the scientific and medical men of the world, and that is cancer. God grant that before long you may be able to find a cure for it, or check its course; and I think that to him who makes the discovery a statue should be erected in all the capitals of the world. In taking leave of you I trust that your stay in London and in England has been an enjoyable one, and that you will one and all carry away pleasant recollections of your visit to my country."

There can be no doubt that the King's desire will be gratified, for, if the foreign delegates have received the some amount of pleasure from the scientific and social work of the Congress as have their British *confrères*, they should go away amply satisfied and with very pleasant recollections indeed. That they were prepared to enjoy everything may be gathered from the fact that they cheerfully, and apparently even willingly, sat through twenty-seven speeches at the final banquet given on Friday night.

The other social features of the Congress were the receptions at the Mansion House by the Lord Mayor, at Apsley House by the Duke and Duchess of Wellington, at the Victoria and Albert Museum by the Earl and Countess of Derby, and at Sion House by the Duke and Duchess of Northumberland; whilst evening parties, private dinners, water parties and the like afforded ample entertainment for all who were able to attend such functions.

Altogether the Congress may be looked upon as one of the most interesting and successful ever held in London, and the results promise to be very far-reaching.

POSITION AND PROSPECTS OF ELECTRO-CHEMICAL INDUSTRIES.

THE presidential address delivered last week by Mr. J. W. Swan, F.R.S., to the Society of Chemical Industry, though it covers the same ground as the one he delivered three years ago as President of the Institution of Electrical Engineers, does so in a much more comprehensive and detailed manner. The paper is very valuable and instructive, though not always pleasant reading for the English electrochemist, who cannot help reflecting that his country is much behindhand in the development of those industries of which Davy and Faraday laid the foundations. It cannot be urged that our backwardness is wholly due to the lack of water power in the British Islands, though doubtless this has contributed in many instances to our failure to keep pace with our competitors. But there are many electrochemical industries in which, though cheap power is by no means essential, other nations have been the pioneers and are likely to reap the reward. Thus, to quote one striking example, there appears to be no English bullion refinery using electrochemical processes, although these are finding extensive employment in America and Germany. The value of the output for 1900 from two out of the three German refineries is given by Mr. Swan as 2,500,000*l.*, the source of power in all three cases being steam.

The fact remains, however, as Mr. Swan points out, that the greater number of electrochemical plants are operated by water power. For fifty European works the figures obtained show that there is 149,000 h.p. available from water, 16,700 h.p. from steam, and 250 h.p. from gas. The great bulk of the horse power generated from water is used in the production of aluminium and calcium carbide, industries in which cheap power is paramount. Is it to be feared, therefore, that the more extended use of electrochemical processes will cause chemical industries to leave this country for others more fortunately supplied with waterfalls? The question is one, as Mr. Swan says, "of national importance, for chemical manufactures occupy, and have always occupied, a leading place among the industries of our country." Something, perhaps much, is to be hoped for from the reduction in the cost of power generated from coal, in which connection we may quote Mr. Swan's words:—

"Great advances have in recent years been made in the direction of reduction of cost, by improvements in the steam engine, the gas producer and the gas engine. In the best modern steam engines a heat efficiency of 15 per cent. is obtained. There is great reason for hope that help in the more economical generation of power for electrochemical work may come from the further development of the gas engine. Already much has been done, both in the improvement of the gas engine and also in providing it with cheap gas. Our honoured past president, Dr. Mond, has made a valuable contribution in this direction.

"One of the drawbacks to the employment of gas engines for large operations has been that they were not adapted for large units of power, but now engines of 500 h.p. and even 1000 h.p. are manufactured, and work with successful results."

It is to be feared, moreover, that we are not only hampered by unfavourable conditions, but that we do not make the most of the opportunities we possess. The position deserves the most careful consideration of all chemists and electricians, or the former will one day awake to find that his purely chemical manufacturing processes have been superseded in other countries by electrochemical methods, and the latter will find, as he has already found largely in electric traction, that, whilst he was sleeping, a new field of development has been fully exploited by American and continental engineers. We cannot help thinking that the fault is, to a considerable extent, due to our educational system and to the bias of the English manufacturer against college-trained men. Mr. Swan's remarks on this point are worthy of very careful attention:—

"In England and Ireland we are suffering acutely from dire educational neglect and destitution, and that worst kind of poverty, *insensibility to our deficiencies.*

"Our English system of scientific and technical education is not equal to the present needs of the country, seeing how severely we are pressed on every side by the most energetic and intelligent competition. We are giving to the classes at the bottom of the industrial ladder a disjointed smattering of miscellaneous science, of no great value, though probably good so far as it goes, while we are neglecting to educate thoroughly those upon whose shoulders will soon rest the weight of the management of our great manufacturing industries. In the present state of things a competent knowledge of the science of the business a man is engaged in, as well as an active interest in it, whether it be chemical industry or any other, are essential conditions of any large degree of success in meeting the emergencies of a highly competitive and progressive time. A scientific training of university standard, for our manufacturers and for our technical chiefs, is an absolute necessity. Surely public money cannot be better spent than in providing adequate facilities for the educational equipment of the men of the future, with this essential means of national defence. Our country possesses great stores of mineral wealth, a precious heritage that we are lavishly spending. That gift of nature will certainly not avert, and cannot go far to compensate for, the consequences of neglect of the scientific training necessary to turn our fast-diminishing mineral wealth to the best advantage.

"One of the most pressing requirements of the moment, demanded, not only in the interest of chemical industry, but in that of our manufacturing industries generally, is *adequate endowment and encouragement of research.* Original scientific research is the fountainhead of new knowledge, the vital stimulus of industrial growth, the originator of new industries and sustainer of old. Yet, nationally, in the organisation of our educational and industrial system, we give to scientific research no hospitality—we barely pay it the respect of recognition."

These arguments have been advanced again and again by educational enthusiasts, but they have as yet borne but little fruit. Perhaps now that they have been so strongly endorsed by one so well qualified to speak from the manufacturer's point of view as Mr. Swan, they may find their way into the minds of those in whose hands lies the future industrial prosperity of England.

MISS ELEANOR A. ORMEROD.

UNIVERSAL regret will be felt at the death of almost our only prominent lady entomologist, and our best authority on farm and garden entomology. Miss Ormerod was born at Sedbury, in Gloucestershire, and breathed her last on July 19, 1901, in her seventy-fourth year, at Torrington House, St. Albans, where she resided for some years with her sister, Miss Georgiana Elizabeth Ormerod, who died in 1896 at the age of seventy-three.

At the time when Miss Eleanor Ormerod turned her attention to injurious insects, no popular English work existed on the subject; for Curtis's "Farm Insects" was too large and costly for wide circulation. We do not know if Mr. E. A. Fitch, who had been projecting a work on the subject himself, suggested it to Miss Ormerod, or whether the initiative came from her; but in 1877 appeared the first part of the well-known "Notes of Observations of Injurious Insects," by E. A. Ormerod, T. A. Preston and E. A. Fitch. About this time Mr. Fitch found that pressure of business prevented him from giving much attention to entomology; but for twenty-three years afterwards appeared annual reports, under the editorship of Miss E. A. Ormerod, embodying the observations of a great number of observers on those species of insects which had been most destructive, or which had attracted special attention during each year. From time to time she published detached observations in different journals on subjects of much importance connected with her favourite subject, supplementary or preliminary to her reports, and she also published several books which had a wide circulation, and some of which went through several editions. Among the most important of her separate works are the following:—"A Manual of Injurious Insects, with Methods of Prevention and Remedy for their Attacks to Food Crops, Forest Trees and Fruit, and with short Introduction to Entomology" (first edition, 1881); "Guide to Methods of Insect Life, and Prevention and Remedy of Insect Ravage" (1884); republished in 1892 under the title of "A Text-book of Agricultural Entomology"; "Notes and Descriptions of a few Injurious Farm and Fruit Insects of South Africa, compiled by E. A. Ormerod, F.R.Met.Soc., &c., with Descriptions and Identifications of the Insects by Oliver E. Janson" (1889); and "A Handbook of Insects injurious to Orchard and Bush Fruits, with Means of Prevention and Remedy" (1898).

Miss E. A. Ormerod was assisted in her work by her sister Georgiana, who was likewise an ardent entomologist, though we are not aware that she ever published anything under her own name. Both the sisters were Fellows of the Entomological Society of London, having joined in 1878 and 1880 respectively, and at one period they were regular attendants at the meetings. For some years Miss E. A. Ormerod held the appointment of consulting entomologist to the Royal Agricultural Society. She was also an examiner in agricultural entomology to the University of Edinburgh; and in 1900 that body conferred upon her the honorary degree of D.C.L.

W. F. K.

NOTES.

THE French Minister of War has asked the Paris Academy of Sciences to give an opinion as to the possibility of danger arising from the establishment of wireless telegraphy stations in the neighbourhood of magazines containing powder or other explosives. It is suggested that the nature of the cases containing the explosive may be an important matter for consideration in connection with the subject.

THREE prizes have been offered to the Marine Biological Association of the West of Scotland by Sir John Murray, K.C.B., in memory of the late Mr. Fred. P. Pullar, who was associated with him in the bathymetrical survey of the Scottish fresh water lochs, and lost his life on Airthrey Loch, Bridge of Allan, in February last. There will be a prize of 50*l.* for a paper on each of the following subjects:—(1) The seasonal distribution and development of pelagic algæ in the waters of the Clyde sea area. (2) The reproduction, development and distribution in the Clyde sea area of the genera Nyctiphanes and Boreophausia. (3) The formation and distribution of glauconite in the deposits of the Clyde sea area and the adjacent seas of Scotland. These prizes are open to investigators from any part of the world who conduct observations in the several subjects at the Millport Marine Station, and who produce, at any time before January 1, 1905, papers which, in the opinion of a committee of three scientific men, to be nominated by the committee of the Association and by Sir John Murray, shall be deemed of sufficient value to merit publication. The honorary secretary of the Association is Mr. John A. Todd, 190, West George Street, Glasgow.

THE annual meeting of the British Medical Association was opened at Cheltenham on Tuesday, when Dr. G. B. Ferguson, the president, delivered an address on "Scientific Research as the Indispensable Basis of all Medical and Material Progress." In the course of his remarks, Dr. Ferguson said that medical progress owed more to the biologists and to the men of pure science than to the so-called practical men. The cell theory, for instance, originated entirely with the biologists. It led up to bacteriology, the most imposing and the most impressive department of medical biology. Bacteriology itself now rested on cultivation and staining; and if year by year more and more of the germs of disease were recognised, it was because of the improved methods of colouring and making them visible. All this strengthened his contention that the basis of modern medicine was essentially scientific. Then in surgery the discovery of the Röntgen rays had been of priceless benefit, but most certainly Röntgen was thinking of nothing less than of surgery when he made that discovery. Antitoxins, which are among the most valuable resources of remedial art, medical men owed to strictly scientific investigators. Personally, he placed much faith in the anti-typhoid inoculations of Prof. Wright, of Netley, and in the anti-tetanus serum, and he felt sure that many more equally effective means would soon be available. Dr. Ferguson next recalled the splendid work—purely scientific again—of the French and Italian investigators of malaria, together with Major Ronald Ross, Dr. Manson, and other English observers, by whom the mosquito theory had been worked out. Turning to ophthalmology, he asked what would have been its state to-day without the invention of the ophthalmoscope by the physicist Helmholtz. Then there was the marvellously successful treatment of lupus by the chemical rays of the electric arc devised by Finsen, of Copenhagen. And where would medical men be without the chemists, who had provided iodine, bromine, iodoform, chloroform, chloral and cocaine? As the result of several visits to the continental capitals he had been struck with the thoroughness and scientific spirit everywhere there manifested, very different from the anti-scientific spirit characterising most of the wealthier and more cultivated classes in this country. France, Germany and the United States educated at their Universities approximately one student in every 1500 of the population, but we were content with less than one in 2000. Yet the matter was one of life or death for the country, for more and more every year the victory and the predominance would pass to the possessors of the latest knowledge, the deepest science and the most perfect and economical processes.

THE Harben medal of the Royal Institute of Public Health was presented to Prof. Koch at the annual dinner of the Institute on July 24. The medal is awarded in recognition of services rendered to the public health, and is conferred irrespective of nationality. In presenting the medal, the president of the Institute, Prof. W. R. Smith, described Prof. Koch's career of scientific activity. In reply, Prof. Koch remarked that when, as a young doctor, he went to take up his practice at Wallstein he found himself in a country where anthrax was to be seen on every hand, and he was naturally led to make the matter one of research. In that research he was greatly assisted by the perfection to which the microscope had been brought, and this gave the key to the wider discoveries in bacteriology that followed. He was gratified to receive the medal as a testimony of their concurrence with the scientific methods which he had followed, and he was all the more pleased to have such an honour from an English institute, because it was in England that his researches in reference to anthrax and the treatment of wounds met with the first appreciation.

PROF. W. A. HERDMAN has received letters and natural history notes from Mr. Nelson Annandale and Mr. H. Robinson, who left Liverpool University College a short time ago for a year's exploration in the Siamese Malay States. Some of the observations made and material collected will be described at the forthcoming meeting of the British Association at Glasgow. Meanwhile, it is interesting to read the following notes from the naturalists:—"We have obtained what is either a second species of Periophthalmus or a genus closely allied to it, and we have to-day ourselves collected a series of young specimens, which show that in extreme youth the eyes are normally placed on the sides of the head, and only migrate to the top later in life. We also got in water less than a fathom a most interesting case of commensalism, in which a small crab, with a very soft back, has the two last pairs of legs specially modified for holding on a sea-anemone, which it grasps by the foot. . . . A good many cases of mimicry between different orders and families, principally between spiders and ants, homoptera and beetles, were noted—in at least ten cases the mimicked animal being an ant."

THE programme of the seventy-third meeting of German Men of Science and Physicians, to be held at Hamburg on September 22-28, has been issued. As there are eleven sections dealing with different departments of natural philosophy, and twenty-seven sections in the group of medical sciences, it is easy for all who are engaged in scientific work to find a section in which they are particularly interested. The general science sections are:—(1) mathematics, astronomy and geodesy; (2) physics, including instrument making and scientific photography; (3) mixed mathematics and physics (electrotechnics and scientific engineering); (4) chemistry, including electrochemistry; (5) general chemistry, including agricultural chemistry and food investigations; (6) geophysics, including meteorology and terrestrial magnetism; (7) geography, hydrography and cartography; (8) mineralogy and geology; (9) botany; (10) zoology; and (11) anthropology and ethnology. On September 23 and 27 there will be general meetings at which lectures will be given. On the former date the lectures to be delivered will be on Hertz electric waves and their further development, by Dr. E. Lecher; the chemical possessions of the cell, by Dr. F. Hofmeister; and the problem of fertilisation, by Prof. T. Boveri. On September 27 the lectures will be on medicine and maritime intercourse, by Prof. H. Curschmann; the significance of electrical methods and theories in chemistry, by Prof. W. Nernst; and on the natural energy of organisms, by Prof. J. Reinke. There will be a joint meeting on September 25 for the discussion on atoms, from the point of view of recent investigations and conclusions on ions and electrons. The president of the meeting is Prof. R. Hertwig, of Munich. Prof. van 't Hoff is the president of the group of natural philosophy sections, and Prof. Naunyn the president of the sections of medical sciences.

THE presidential address delivered by Mr. G. C. Druce at Dublin on Tuesday, at the opening meeting of the British Pharmaceutical Conference, was a survey of the important scientific discoveries made during last century, and their relation to the art and practice of pharmacy. In pharmaceutical chemistry, the active principles which have been isolated are now appalling in number, and have assisted in making great changes in the character of dispensing. In addition, a stream of artificial compounds, many of which possess marked therapeutic action, has flowed from the laboratory of the chemist. Referring to botany and systems of classification, Mr. Druce said: "One marked change has taken place during the past century so far as the professional teaching of botany is concerned, for in the early years of last century all the important botanical chairs in Britain were held by systematists, now not a single one is so occupied. This is not an unalloyed advantage. That systematic botany alone should be taught to the almost absolute neglect of histology or physiology was doubtless an evil, and it has been said that taxonomic teaching was choked by its own nomenclature; but the whirligig of time brings its revenges, and now we may without injustice retort that laboratory botany is being strangled by the exuberance of its terminology. And the positive evil exists that with the neglect of systematic teaching in Britain our continental and transatlantic *confrères* are occupying the ground in which Britain for long held a foremost position, and which, from the extent of our colonial possessions, should be especially its own."

DR. CARL PETERS has returned to London, after an extended journey from the Zambesi to the Sabi rivers, and has brought home news of interesting archæological discoveries on the frontier of Mashonaland. One of these is a small female figure of Egyptian workmanship, which is believed to date back to 2500 years before the Christian era. There have also been found thirty-three copper and six silver coins and a couple of stones bearing inscriptions. It is hoped that a scientific expedition will be sent out to make further investigations.

WE learn from the U.S. *Monthly Weather Review* that the German South Polar Expedition will systematically make kite ascensions in the trade winds from aboard ship during the southward journey, and continue the work in the Antarctic regions. The expedition is fully equipped with suitable apparatus, all substantially of the Weather Bureau pattern, and the scheme will be that followed at Washington, with modifications required by the conditions and resulting from extensive experiments at the Deutsche Seewarte. The kites are of three sizes, the large Marvin of $6\frac{1}{3}$ square metres surface, Hargrave kites of 4 and $2\frac{3}{4}$ square metres surface and light Eddy kites of $2\frac{3}{4}$ square metres, which are very advantageously employed in lifting and sustaining the larger kites with the instruments in light winds. This appears to be the first occasion on which preparations have been made for the systematic exploration of the upper air conditions in the polar regions.

AFTER a protracted spell of dry weather, London was visited by a violent thunderstorm about noon on July 25. The weather chart issued by the Meteorological Office on that day showed that a shallow depression lay over the south-eastern parts of England, and this moved very slowly to the westward during the next few days. Except that the conditions were very unsettled there was nothing to indicate the occurrence of a storm of unusual violence. The rainfall was of great intensity, amounting to nearly an inch and three-quarters in about an hour and a half, and to three inches within forty-eight hours. In some parts of the metropolis much damage was caused by flooding, and railway traffic was suspended for a considerable time. As late as Sunday last this same shallow storm area was still lingering over the southern portion of the country, the centre being in the morning in the south-west. Heavy thunderstorms were still occurring in those parts which lay near the path of the disturbance. On Saturday there was again exceptionally heavy rain in parts of London, an inch falling in less than an hour in the southern suburbs. The midland districts of England have experienced very heavy rains, the fall at Oxford amounting to 4·33 inches in the four days ending last Sunday morning.

WE have received from Dr. W. Doberck, director of the Hong Kong Observatory, a copy of the observations made there during the year 1900. The work contains, in the same form as in previous years, a very valuable series of hourly meteorological observations and mean results deduced from them, as well as magnetical and astronomical data. In addition to the usual work of a well-equipped observatory, much attention is given to various researches, including the collection of observations at about forty land stations and from ships' logs, with the view of contributing to our knowledge of the climatology of the Far East and of the destructive typhoons of the eastern seas. The total number of days' observations collected from different ships during the year amounted to nearly 20,000; these are regularly entered in degree squares for the construction of trustworthy pilot charts. Weather forecasts are also issued daily about 11h. a.m., and a comparison with subsequent weather shows that the amount of total or partial success reached the high figure of 93 per cent. during the year in question.

THE Meteorological Office Pilot Chart of the North Atlantic and Mediterranean for the month of August shows that there has been a very decided increase in the quantity of ice in the neighbourhood of Newfoundland, the reports, which are as late as July 3, being too numerous to admit of all being given on the chart. The bergs crowd mostly from Cape Race eastward to the Flemish Cap, but there are a good many scattered about down to 42° N., 49° W. and 43° N., 43° W. In the notes on the winds, further information is given relating to West Indian hurricanes, some of which, there is reason to believe, originate in the neighbourhood of the Cape Verde Islands, where the prevailing winds for August exhibit a cyclonic circulation. To the mean path of these hurricanes is added an indication of the southern and the eastern and northern limits within which they have been experienced in this month, the South American coast westward to Honduras being practically free from actual hurricanes, but experiencing very disturbed seas, occasioned by the distant gales. In Trinidad, the hurricane months are marked by violent squalls and heavy rain. The region of ordinary gales has commenced to work southward after having nearly disappeared northward in July. After steadily extending eastward from the American coast until the Bay of Biscay was reached in July, the fog area has suddenly shrunk, the main area being now to the westward of the 30th meridian, only a small patch being shown off the English Channel; but it is stated that while there is this diminution off our south-western coasts there is an increase in progress up the east coast of Britain and about the Clyde and Irish Sea. Other notes deal with the salient features of the ocean currents; with British thunderstorms which form locally; and with the winds of the Sea of Marmara, and currents of this sea and the Dardanelles and the Bosporus.

THE Report of the Council issued in the *Proceedings* of the South London Entomological and Natural History Society for 1900 discloses a satisfactory state of the roll of members and of the finances of that energetic body. The average attendance at the meetings has been about 30, which is remarkably good for a society whose members number only 170. Mr. R. Adkin communicates an interesting article on the life-history of the goat-moth, in which it is shown that the change from caterpillar to chrysalis does not take place in the stems of the living willows tunnelled by the former, but rather in dead trunks or any other situation where soft, friable matter is to be met with.

A VIEW of M. Fagel's statue of Chevreul, unveiled at Paris on July 11, is given here by the courtesy of the *Chemist and Druggist.* The monument stands in the Cour d'Honneur of the Paris Museum of Natural History, and is an excellent representation of the eminent chemist, whose investigations have greatly assisted in promoting the commercial prosperity of France. The base of the statue bears inscriptions recording the principal events of Chevreul's life, the front one being as follows:—"Chevreul, Michel-Eugène, né a Angers le 31 aout 1786; mort a Paris le 7 Avril 1889. Professeur de Chimie

Statue of Chevreul.

Organique, 1830–1889; Directeur du Muséum d'Histoire Naturelle, 1863–1884." Upon the occasion of the unveiling of the statue, M. E. Perrier, the present director of the Paris Museum of Natural History, delivered an address which is given in full in the *Revue Scientifique* of July 20, with discourses by M. A. Gautier, who represented the Academy of Sciences, and M. Arnaud, who succeeded Chevreul in the chair of organic chemistry at the Museum in 1890.

THE latest issue of *Notes* from the Leyden Museum contains an article by Dr. F. A. Jentink on the collection of antelopes in that institution, in the course of which the author pays a tribute to the value of the "Book of Antelopes," by Messrs. Sclater and Thomas. The Leyden collection appears to be very rich in antelope skins from the Cape, many of these belonging to species which are at least locally extinct. The author believes the white-tailed gnu to be quite extinct as a wild species, and the same is true for the eland in Cape Colony. The head of a female of the latter with an abnormal form of horn is figured. In the same journal Dr. Finsch continues his catalogue of the Leyden bird collection, dealing in this section with the bee-eaters.

ANOTHER ruminant—the Louisianian representative of the white-tailed deer—receives a new name in the June number of the *American Naturalist.* Recently some American writers announced that the proper specific name of the Virginian white-tail was *americanus*, instead of the time-honoured *virginianus*, and the former name has consequently been generally adopted in literature. Others say they were wrong in the change, and propose to revert to *virginianus.* Nothing can be more unsatisfactory than such perpetual changes, and it is far better to adhere to one name, even if it be not what is called the right one. To the same journal Dr. R. W. Shufeldt contributes a paper on the affinities of the American birds commonly known as screamers (Palamedeæ). While admitting their affinity with the duck tribe, he suggests that they may be the survivors of the common ancestral type of both the anserine and the gallinaceous birds. In all their characters these birds are archaic, and the author is of opinion that they serve to connect the duck tribe with the ostrich group.

IN launching a new periodical, the *Museums Journal*, of which the first number is dated July, the Museums Association has full justification, and the venture has our best wishes. It is edited by Mr. E. Howarth, of Sheffield, with the cooperation of other museum officials from England, Germany, the United States, Australia, the Cape and New Zealand; and by this wide basis any danger of cliquism gaining a predominance in the new journal should be obviated, while it will ensure attention to the needs of museums in all parts of the world. Following the introductory notice is an address on the museums of Edinburgh by Sir William Turner, the president of the Museums Association, whose portrait forms the frontispiece to this issue. Next comes a specimen museum label, to be followed by others month by month. This label, which deals with British pottery, is, in our opinion, too long and too verbose. In order to avoid wearying museum visitors, it should clearly be divided into two—the first descriptive and the second dealing exclusively with the various British potteries. The part closes with a series of general notes, of which one section is devoted to home and the other to foreign museums.

SOME interesting conclusions have been arrived at by Dr. Ford, of the McGill University, Montreal, in the course of his investigations on the bacteriology of the healthy organs of animals. The liver and kidneys of a number of rabbits, guinea-pigs, cats and dogs were examined, and at least eighty per cent. were found by Dr. Ford to contain bacteria. This is contrary to the results obtained earlier by Neisser and Opitz, who in similar examinations found no bacteria. This apparent discrepancy in the two series of investigations is explained by Ford as due to Neisser and Opitz only cultivating the organs examined by them for two, at most three, days, whereas it is necessary, Ford states, to leave them for several days, a week, and even two weeks to obtain the development of the bacteria present. Each animal, regardless of its species, showed its distinct bacteriology, and as a rule the Carnivora—dogs and cats—exhibited bacteria similar to each other, but absolutely different from those obtained from the Herbivora—rabbits and guinea-pigs. These results are quite consistent with the difference in the food used by the animals, which would determine to a large extent the intestinal flora. Dr. Ford's paper is published in the *Transactions* of the Association of American Physicians.

The *Revue générale des Sciences* for June 30 and July 15 contains an article by Dr. Cureau on the geography of equatorial Africa. The subject is well treated in its most general aspects, and a number of interesting sections, particularly of the Nile-Congo region, are given. The second article deals with the population.

THE new number of the *Mitteilungen aus den deutschen Schutzgebieten* contains two important series of determinations of heights in Togoland. Dr. A. Lübbert contributes a paper on native treatment and medicines in German South-west Africa, and a report on the system of land surveying employed in Cape Colony and its application in modified form to German South-west Africa. From German East Africa Captain Prüssing writes on the Rufiyi delta, and Dr. Kandt on Ruanada. Dr. Pflüger contributes some notes on the geology of the Bismarck Archipelago.

The *Zeitschrift* of the Berlin Gesellschaft für Erdkunde contains an important report by Dr. von Oppenheim on his journey in Asiatic Turkey during 1899. The region traversed is of special interest in relation to the proposed railway from Constantinople to Bagdad, and the paper discusses the best available route for such a railway, and the prospects of its financial success. Dr. W. Brennecke gives, in the same number of the *Zeitschrift*, the results of Prof. Philippson's determinations of heights in the neighbourhood of Pergama.

In *Petermann's Mitteilungen*, M. Gentil-Tippenhauer continues his papers on the geology of Haiti. The present instalment deals with the mineral deposits of Terre-Neuve and Gonaives. Prof. Supan contributes a paper, read at the recent Geographentag at Breslau, on the climate of the Antarctic, in which he discusses the results of recent observations as establishing the existence of a permanent polar anticyclone, surrounded by a ring of low pressure. Dr. Franz Schaffer gives an account of studies in the geotectonics of south-eastern Anatolia, made during journeys in the spring and autumn of 1900.

THOSE of our readers who are interested in the Farthest East should consult the *Mittheilungen der deutschen Gesellschaft für Natur- und Völkerkunde Ostasiens* (Tokyo, also at Asher and Co., Berlin). In vol. viii. part 2 of that journal will be found an account of the existing and proposed state and private railways in Japan, by Inspector F. Baltzer. The ancient national bon-festival is described by Dr. H. Weipert and illustrated by nine plates drawn by Japanese, which present existing and former aspects of certain ceremonies and dances connected with the festival. The bon-dance has been handed down from the mythical period, and the primitive Ainos have a very similar dance. The Rev. A. Lloyd has a paper, in German, on dogmatic anthropology in Buddhism. Prof. Aoyama writes on the plague. The number concludes with a short communication by Prof. Dr. E. Bälz on the racial elements in Eastern Asia, especially in Japan. He characterises (1) the Mongolo-Malayan type; (2) the Korean-Mandschurian type; (3) the Aino type. The latter are, according to Bälz, the remains of a "Caucasian or Caucasoid race" that was widely scattered throughout the whole of the north of Asia.

THE current volume (vol. iii.) of the *Bulletin* of the Free Museum of Science and Art of the University of Pennsylvania has several interesting articles, mainly on collections that have been presented to the Museum. We have previously directed attention to this Museum, which has greatly prospered under the curatorship of Mr. Stewart Culin, and is rapidly becoming an important centre of research and instruction. A copiously illustrated account is given by Mr. Culin of a summer trip among the Western Indians, being a narrative of the Wanamaker Expedition. In addition to much interesting information gained on this trip, large numbers of specimens were obtained, many of which were of objects the use of which has all but died out. Pendant-shaped stones with a groove encircling one end are constantly found in America in graves and elsewhere. These are popularly called "plummets." The so-called "plummets" form the subject of an illustrated paper by Charles Peabody, who enumerates the numerous uses to which these stones have been supposed to be put. Of these supposititious uses that as true plummets is the most unlikely; probably most were sinkers used in fishing and some were weights used in weaving, while others were probably used for various purposes. The indefatigable travellers, Dr. H. M. Hiller and Dr. W. H. Furness, 3rd, give an illustrated paper on the Veddahs of Ceylon, but there is nothing particularly new in their observations. The games of the Ogalala Indians are fully described by Mr. Louis L. Meeker; these Amerinds are a branch of the Sioux, and the specimens he collected further enrich the unique collection of toys and games that Mr. Culin has been the means of garnering in the Museum under his care.

AMONG the series of useful French handbooks published under the title of *Scientia*, there are few that will prove of greater interest to mathematicians and physicists than M. J. Hadamard's volume of 102 pages on Taylor's series and its extension. The general problem of Taylor's series consists in the determination of an analytical function by the solution of the following problems: (1) calculation of the function at any point whatever; (2) determination of the singular points. M. Hadamard considers that the solution of the first problem is to be found in Mittag Leffler's theorem, but that of the second is at present in a much less advanced stage. In the bibliography, the author gives a list of more than a hundred books and papers dealing with the properties of analytic functions, the convergence of series and other questions arising out of the general problem.

IN the *Psychological Review* (viii. 2), Prof. G. T. W. Patrick studies the questions, "Why do men swear? When they swear, why do they use the words which they do?" From a classification of the various forms of profane expression used by men at different periods of history, and an examination of their connection with religious words, the writer concludes that profanity is not to be regarded as primarily an expression of emotion, but is only to be understood by the genetic method, the point of departure being the growl of anger in the lower animal, which is a serviceable form of reaction in cases of combat. It belongs, therefore, to a primitive form of vocalisation, and hence is ancient and deep-seated, being one of several forms of speech preceding articulate language by an indefinite period of time. By a process of selection it chooses at all times those forms of phonation or those articulate words which are best adapted to terrify or shock the opponent. Although originally useful in combat, the occasion of profanity at the present time may be any analogous situation in which our well-being is threatened, as in helpless distress or disappointment. If, then, the oath is a form of instinctive reaction and even a purifying agent, why is it considered to have an immoral quality? Prof. Patrick thinks for two reasons: first, because advancing civilisation bids us evermore inhibit and repress; and, secondly, because of the unfortunate but inevitable connection between profanity and the sacred names of religion.

AN account of the new eruptive cone on Vesuvius, which commenced to form in September, 1900, up till April last, is given by Prof. E. Semmola in the *Rendiconto* of the Naples Academy (vii. 4). The cone is—or rather was at that time—about forty metres high, but difficult of ascent owing to its steepness and the thick coating of sand on its walls. The internal cavity was irregularly elliptic and was divided along its major axis into two parts. In that part lying towards the north-east a crater had been formed whose depth did not appear to exceed twenty-five metres; at its bottom was the eruptive aperture emitting a copious column of vapour and gas. In the smaller portion was a crateriform dyke, full of cracks, and with the walls smoking in places, this being separated from the crater previously mentioned by a kind of wall rising half-way up and terminating in the floor of the crater. The internal walls of the crater were carpeted with sublimates, in which various shades of red and yellow predominated. The vapour made its exit in globular clouds, which in calm weather spread out into a fine tree-shape some hundred metres high. The gaseous products reddened litmus paper, and here and there sulphurous anhydride was noticeable; the ground at the top of the cone felt hot, and the temperature at a depth of 50 cm. was about 50° C. Reflected light was not seen at night, and Prof. Semmola hence concludes that the source of activity was at a considerable depth. The general character of the phenomena, and in particular the entire absence of explosions or ashes or projected bodies, points to the activity of Vesuvius being considerable, but the channels of activity being altogether free from any obstructions such as would cause violent action to take place.

MR. RAVENSHAW'S paper on the electrical transmission of power in coal mines, and Mr. Walker's on electrical miners' safety lamps, which appear in the last number of the *Journal* of the Institution of Electrical Engineers, contain, with the joint discussion on the two papers, a great deal of valuable information on this comparatively recent application of electricity. The number of purposes to which electricity can be applied, either to supply an existing want or to replace some less satisfactory method, is continually increasing, and as each new problem is attacked special difficulties present themselves. This is very apparent in this instance, where the dangers peculiar to coal-mining make it essential for the electrician to design special machinery to meet the case. Mr. Walker's paper is very instructive as showing how many difficulties have to be overcome before a lamp can be obtained to compete at all successfully with the existing miner's lamp, although at first sight the electric lamp would seem to be so preeminently the best one to use. Thus, apart from questions of cost and weight, the very safety of the electrical lamp is in itself a drawback, since it does not indicate, as does an oil lamp, the presence of dangerous gases. There can be little doubt, however, that the difficulties have only to be fully realised to be successfully overcome, and in the course of time the use of electricity is likely to become general in coal-mines, for which in essential respects it is so peculiarly suitable.

A FEW more details concerning the adoption of the "Parsons steam turbine" as a source of propulsion in the mercantile marine are now available. The vessel named the *King Edward*, the main dimensions of which have been given in a previous number, has been launched and (says *Engineering* of July 5) has so far quite realised the expectations of her owners. The trials were run on the Firth of Clyde, where, on a mean of runs "over the Skelmorlie mile," the speed of 20·48 knots was obtained. The mean revolutions were registered at 740 per minute, boiler pressure 150 lbs. per sq. inch, a vacuum of 26½ inches, and a stokehole pressure (forced draught) equivalent to one inch of water. Among the advantages of the Parsons steam turbine over the ordinary reciprocating engines the following are mentioned:—(1) The weight of the propelling machinery is 66 tons, being, it is stated, roughly half the weight for an engine (of the same power) employed in a paddle steamer of the same type. (2) On account of the lightness of the turbine machinery, very graceful lines have been introduced into the "model" of the hull, both fore and aft, which otherwise could not have been used. (3) The small amount of room taken up by the turbine machinery. All the machinery is placed below the "main" deck, giving the space above otherwise occupied with engines to additional passenger accommodation. (4) The total absence of noise from the turbines when running. In fact it is stated that it is not possible to tell whether they are running or not; by placing one's hand on them the only slight vibration discernible is right aft, and is due to the propellers. (5) The low centre of gravity of the turbine machinery has given good stability in the *King Edward* without either a "hard bilge or long floor," rendering this class of machinery conducive to high speeds. During the trials Rothesay was "made" as an experiment, and the vessel behaved splendidly, coming to easily and quickly—an important point in passenger excursion traffic, for which the steamer is intended. The *King Edward* is now on her run in Scotland, and is by far the fastest boat of her class.

WE have received from Messrs. Baker and Co., of Newark, U.S.A., an illustrated catalogue of platinum apparatus for use in large and small college chemical operations. The illustrations show a variety of useful contrivances for laboratory purposes, and the catalogue concludes with some valuable observations on the use and care of platinum, on the cleaning of platinum wire, and with some tables which will much assist in calculating the weight, and therefore the price, of platinum apparatus.

THE popular science lectures for young people, which have been given at the Kensington Town Hall during the autumn and winter, will be continued in October next. The aim is to interest juveniles in various aspects of scientific study and encourage them to view natural objects and phenomena in a sympathetic frame of mind. The subjects of lectures arranged for the autumn are secrets in sands, by Mr. C. Carus-Wilson; waves of sound and waves of light, by the Rev. J. O. Bevan; colour and colour photography, by Dr. A. H. Fison; flowers and their insect visitors, by Prof. J. B. Farmer, F.R.S.; and secrets in flint pebbles, by Mr. C. Carus-Wilson.

MR. EDWARD STANFORD has published a South Polar chart which will be of service in following the progress of the expeditions about to sail for Antarctic regions. The chart indicates, by contours and eight shades of blue, the ocean depths, so far as they are known, down to 5000 fathoms and below. Lines are also engraved on the chart to show the approximate limit of the pack ice during the southern summer months, the line of freezing-point in air in January and February, the northern limit of icebergs, and the tracks of the *Challenger*, *Valdivia* and *Belgica* expeditions. It is a little to be regretted that the proposed tracks of the expeditions about to start are not also included, so that the fields of operations of the German and British expeditions could be easily distinguished.

THE paper by Prof. S. P. Langley and Mr. F. W. Very, "On the Cheapest Form of Light," which appeared in the *American Journal of Science* in August, 1890, has been reprinted and published as No. 1258 of the Smithsonian Miscellaneous Collections, with a note pointing out some of the additions to our knowledge of the light from living and mineral sources during the last ten years. It will be remembered that the paper deals with the light of the fire-fly and shows that the insect produces light without heat, so that its efficiency as a light source is far higher than any artificial means of illumination. In connection with this subject, the luminous bacteria cultivated by Mr. J. E. Barnard and Prof. Allan Macfadyen, and shown at the last Royal Society conversazione (see p. 57) are of interest.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. Crandon W. Gill; an Alpine Marmot (*Arctomys marmotta*), European, presented by Mrs. Curtis; a Rough-keeled Snake (*Dasypeltis scabra*), four Rhomb-marked Snakes (*Trimerorhinus rhombeatus*, four Rufescent Snakes (*Leptodira hotamboeia*), three Crossed Snakes (*Psammophis crucifer*), a Coppery Snake (*Prosymna sundevalli*), a Delalande's Lizard (*Nucras delalandii*) from South Africa, presented by Mr. A. W. Guthrie; two Pond Herons (*Ardeola grayi*), a Cattle Egret (*Bubulcus coromandus*), a White-bellied Drongo (*Dicrurus coerulescens*), a Common Hawk Cuckoo (*Hierococcyx varius*), two Baya Weaver-birds (*Ploceus baya*), two Scarlet-backed Flower-peckers (*Dicoeum cruentatum*), two Purple-rumped Sun-birds (*Arachnechthra zeylonica*), a Himalayan Black Bulbul (*Hypsipetes psaroides*) from British India, presented by Mr. E. W. Harper; two European Pond Tortoises (*Emys orbicularis*), European, presented by the Hon. Mrs. Fitzgerald; an Algerian Tortoise (*Testudo ibera*) from North Africa, three South Albemarle Tortoises (*Testudo vicina*), two Central Albemarle Tortoises (*Testudo*, sp. inc.) from the Galapagos, deposited; two Herring Gulls (*Larus argentatus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN AUGUST.

August 2. 2h. Mercury at greatest elongation, 19° 23′ West.
4. 14h. 39m. to 15h. 47m. Moon occults δ Piscium (mag. 4·6).
6. 12h. 16m. Minimum of Algol (β Persei).
9. 9h. 5m. Minimum of Algol (β Persei).
11. Maximum of Perseid meteoric display (radiant 45° + 57°).
13. Saturn. Outer minor axis of outer ring = 17″·94.
15. Venus. Illuminated portion of disc = 0·873, of Mars = 0·915.
15. 7h. 21m. to 10h. 26m. Transit of Jupiter's Sat. III. (Ganymede).
17. 6h. 12m. to 8h. 32m. Transit of Jupiter's Sat. IV. (Callisto).
25. 6h. Saturn in conjunction with the moon. Saturn 3° 42′ S.
28. 12h. 54m. to 13h. 59m. Moon occults c′ Capricorni (mag. 5·2).
29. 12h. 29m. to 13h. 29m. Moon occults κ Aquarii (mag. 5·5).
29. 10h. 47. Minimum of Algol (β Persei).

THE PARIS OBSERVATORY IN 1900.—A Paris correspondent sends us the following note:—The annual report drawn up by M. Maurice Lœwy, director of the Paris Observatory, and adopted by the Observatory Council, has been sent to the National Printing Office for publication. The international mapping of stars not being in operation in three different parts of the southern hemisphere, M. Lœwy, president of the committee, has sent representations to these countries, through diplomatic agencies, with the result that work will soon begin in them. Mr. Thome, director of the National Observatory, Cordoba, has written to M. Lœwy that the Argentine Republic has authorised him to organise an astrophysical service. Mr. Cooke, director of the Perth Observatory in Southern Australia, has been notified by the Colonial Office that a special grant will be at his disposal for the future budget. M. Enrique Legrand, of the Uruguay Republic, has persuaded H.E. M. Cuertas to present a bill for the establishing of an astrophysical service in Montevideo. The work is progressing favourably in all the countries where it has been inaugurated.

M. Lœwy is investigating Prof. Turner's method of determining, from photographs, the positions of the celestial bodies with almost the same exactness as from direct observations in the sky. The report gives for the first time a complete list of the fifty-eight observatories which have taken part in the Eros international observations. According to the last news included in the report, January 6, no single night had passed, since the inauguration of this work, without at least one observatory having made at least one Eros observation. On favourable nights the number of observations exceeded one hundred. MM. Prosper Henry and Boinot took 104 series of photographs of the planet Eros from October 3 to January 6.

Six hundred and seventy stars at a distance of not more than one degree from the path followed by Eros were observed with the meridian circle. For the first time observations of stars were registered on the meridian with a special chronograph invented by the Abbé Verschaffel. Ten sheets, containing 16,500 stars, of the photographic catalogue of the heavens, have been published. Each of these sheets contains a zone of one degree in declination and eight minutes in Right Ascension. Photogravures for the Lunar Atlas have been prepared for publication; they refer to the first and last quarter. On the occasion of the total eclipse of May 28, MM. Hamy and Bigourdan were sent to Spain and were favoured with splendid weather for their observations. M. Bigourdan continues his observations of nebulæ, and the work of his great catalogue is progressing favourably. M. Callandreau observed with the great equatorial of the western tower, and used a wire illuminated only by points in the field of his refractor; he appears to be satisfied with this method, which prevents the eye from being disturbed by too great a quantity of light when observing feeble stars.

M. Gaillot has worked at the theory of Saturn, using Le Verrier's formulæ, and has succeeded in showing that the discrepancies between the results of computation and observation should be attributed to the fact that a sufficient number of terms had not been taken into consideration.

A staff of six women observers, directed by Miss Dorothea Klumpke, has determined the position of 29,627 stars for the International Catalogue. This is the only department of the Observatory where ladies have been admitted. To the meteorological department a new registering barometer has been added; it is a mercury one, and the end of the index runs through 3 mm. for a variation of 1 mm. in mercury. The publication of the old observations from 1837 up to 1886 will be completed this year, and from 1886 on the observations will be published regularly each year. The observations of 1898 were published in 1900, and those of 1899 will appear shortly.

PHOTOGRAPHY BY THE LIGHT OF VENUS.—In the autumn of last year several meagre accounts appeared in various journals announcing that Dr. W. R. Brooks had succeeded in obtaining good photographic records solely by means of light from the planet Venus. In the *Century Magazine* for August (1901), Dr. Brooks has an article describing his experiences, illustrated by reproductions of the photographs obtained at the Smith Observatory. These are chiefly positives taken by placing a landscape or other negative in a printing frame with a sensitive plate and exposing to the light from the planet, care being taken to shield the frame from all extraneous light. The results described were obtained when the planet was a morning star, shortly after September 17, 1900. Gelatine dry plates (speed not stated) were used, the exposures given varying from thirty to forty-five minutes. A print on bromide paper was obtained by exposure on five consecutive clear mornings. The positives are all apparently well exposed, and a portrait is also shown as being produced by the planet's light, but by what procedure is not indicated.

NEW NEBULÆ.—In the *Comptes rendus* (cxxxiii. pp. 206–208), M. Bigourdan continues his catalogue of new nebulæ discovered with the west equatorial of the Paris Observatory. Particulars as to position, notes of special interest and comparisons with other catalogues are given for twenty-three objects observed between 1884 and 1898.

THE CRYSTALLISATION OF SALT SOLUTIONS.

ALTHOUGH the processes of crystallisation have been known to, and made use of by, chemists for ages, yet it is only within the last few years that the phenomenon of crystallisation from solution has been the subject of systematic investigation. The pioneer work in connection with this systematic study on the basis of modern principles has been done, for the most part, by Dutch chemists. The researches of Roozeboom on the equilibrium of systems in contact with water have shown clearly the importance of the phase rule of Willard Gibbs as a guide in the study of the complex phenomena of heterogeneous equilibrium. The study in van 't Hoff's laboratory of the conditions of existence of crystallohydrates and of the phenomena associated with the formation and decomposition of double salts in contact with water has given us invaluable material for a correct understanding of the processes of crystallisation. Not only is the systematic investigation of this phenomenon of importance to the chemist, but the geologist is also dependent on such knowledge for the final explanation of the conditions of formation of the vast oceanic salt deposits.

A knowledge of the composition of the solution in equilibrium with a system of solid substances is obviously an all important factor for the study of the processes of crystallisation, for the separation of any solid substance from the solution requires that the solution shall be saturated with regard to that substance. In what follows it is presumed that the crystallisation takes place so slowly that supersaturation phenomena can be neglected, and the complications resulting from crystallisation of isomorphous mixtures are also left out of account. Furthermore, we suppose that the temperature of the solution remains constant during the crystallisation.

The simplest conditions are then met with in the case of a solution containing a single substance, say a salt, which is not capable of combining with water of crystallisation. If an unsaturated solution of such a salt is evaporated, the commencement of crystallisation is conditioned solely at a given temperature by the attainment of a definite concentration. As evaporation proceeds the salt then separates out continuously, the composition of the solution undergoing no change until the last trace of water has been removed.

If the dissolved salt forms crystallohydrates, *i.e.* salts with water of crystallisation, then the products of isothermal evaporation are dependent upon the temperature, a less hydrated form separating as the temperature is higher. Thus solutions of manganese chloride yield the tetrahydrate if the temperature does not exceed 58° C., whereas at higher temperatures the dihydrate crystallises out. It is well known that salts containing water of crystallisation undergo at a definite temperature a change in which the whole or part of the water of crystallisation is split off. Glauber's salt loses its ten molecules of water at 32·4° C.; ordinary zinc sulphate containing seven molecules of water yields the hexahydrate at 39° C., and this again, at a higher temperature, yields a lower hydrate. These temperatures are known as the transition temperatures of the salt hydrates, and have a far-reaching analogy with the melting points of solid substances.

The limiting temperatures corresponding to the crystallisation of a definite hydrate from the salt solution are determined by the transition temperatures of the solid hydrates.

If supersaturation phenomena intervene we may observe the separation of hydrates from solution at temperatures below the normal limiting temperature. It is, however, only under this condition that crystallisation of such unstable hydrates takes place, for at a given temperature the unstable hydrates are more soluble than the stable hydrate. If the solution from which an unstable hydrate has begun to crystallise out be impregnated with the hydrate of smaller solubility, the unstable hydrate will redissolve and crystallisation of the normal hydrate ensues

If a solution contains two dissolved salts having a common ion, the phenomena of crystallisation are about as simple as in the case of a solution containing a single salt. Let us suppose, in the first instance, that these salts do not unite to form a double salt, and that they do not form crystallohydrates. Such a solution is one containing the chlorides of sodium and potassium, and in this case a knowledge of the composition of the three solutions, saturated respectively with regard to each single salt and with regard to both simultaneously, enables us to predict what will take place on isothermal evaporation. A graphic representation of the solubility data facilitates the tracing of the crystallisation process very considerably, and the composition of the various solutions is conveniently expressed by the number of molecules of dissolved salt per 1000 molecules of water. Fig. 1 contains the data for the system consisting of water, potassium chloride and sodium chloride at 25° C., A representing the saturated solution of sodium chloride, B that of potassium chloride, and C the solution saturated with regard to both.

Along the curve A C we have solutions saturated with regard to sodium chloride in which the potassium chloride concentration gradually increases. Similarly, the points along the curve B C represent solutions containing increasing quantities of sodium chloride, all of which are saturated with reference to potassium chloride.

All points within the figure O A C B represent unsaturated solutions, the quantities of the dissolved salts being given by the lengths of the projections on the axes. If a solution corresponding to the point *c* is slowly evaporated at 25° C., the change in the composition of the solution will be represented by the continuation of the line O *c* (O corresponding to pure water). At the point *d*, where this line meets the curve B C, the solution becomes saturated with potassium chloride and the latter crystallises from solution. By the continued separation of potassium chloride the relative proportion of sodium chloride in the solution increases, and the composition of the solution is represented successively by points on *d* C. At C sodium chloride begins to crystallise and the two chlorides are then deposited in the proportions determined by the position of C on the diagram until the evaporation is complete. The arrows indicate the course of crystallisation for any given solution.

The phenomena of crystallisation may be somewhat more complicated if the two salts in solution are capable of double salt formation. Whether the double salt crystallises out on evaporation depends essentially upon the temperature. For example, the evaporation of a solution containing the chlorides of calcium and magnesium yields a mixture of the simple salts below 22° C., whereas at a higher temperature the double salt, tachhydrite, $CaCl_2.2MgCl_2.12H_2O$, accompanied in general by one of the simple salts, crystallises out.

Let us consider the crystallisation of a solution containing the sulphates of magnesium and potassium at a temperature of 25° C., this lying between the limiting (transition) temperatures at which the double salt, schönite, $K_2SO_4.MgSO_4.6H_2O$, is formed and decomposed.

The solubility data which furnish us with fixed points by means of which the course of crystallisation is determined are in this case four, viz., the saturated solutions of (1) $MgSO_4.7H_2O$, (2) K_2SO_4, (3) schönite and $MgSO_4.7H_2O$, (4) schönite and K_2SO_4.

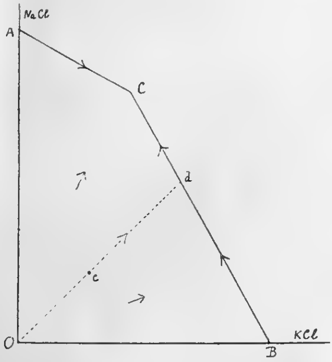

FIG. 1.

In Fig. 2, where potassium sulphate is measured off on the abscissa and magnesium sulphate on the ordinate, these solutions are represented respectively by the points A, B, C and D. The connecting curves have the same significance as in Fig. 1.

Suppose we slowly evaporate at 25° C. a solution the composition of which is given by the point *a*, which lies on the line bisecting the angle between the axes; this solution obviously contains equivalent quantities of potassium and magnesium sulphates. The index point representing successive conditions of the solution advances along the continuation of O *a* until the point *b* is reached, when the solution becomes saturated with potassium sulphate. As evaporation continues and crystallisation of potassium sulphate takes place we advance along *b* D until at the latter point the solution becomes saturated with regard to schönite. On further loss of water schönite crystallises out, and since the molecular concentration of magnesium sulphate in the solution is greater than that of potassium sulphate, the continued separation of the double salt increases the molecular ratio $MgSO_4 : K_2SO_4$ in the solution, corresponding to a movement of the index point along D C, the curve of saturation of the double salt. If the solution were agitated so as to bring the separated K_2SO_4 into intimate contact, some of the latter would again pass into the solution and reappear as schönite. At the point C the solution becomes saturated with regard to $MgSO_4.7H_2O$, and Epsom salts and schönite now crystallise out together until the solution completely disappears. The point C represents the crystallisation end point of all solutions containing magnesium and potassium sulphates, the final separation from all such solutions being a mixture of schönite and Epsom salts. The arrows in the figure show the course of the crystallisation for any solution.

If we now suppose that one of the two salts is capable of dehydrating the other when the solution becomes concentrated, the products of crystallisation which are first separated may undergo a series of successive transformations. If the two salts in solution do not unite to form a double salt, as in the case of magnesium sulphate and magnesium chloride, the

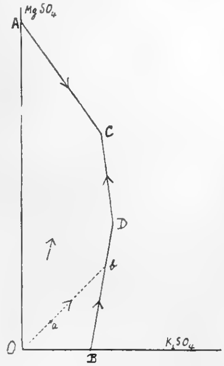

FIG. 2.

phenomenon to be discussed appears in its simplest form. It may be pointed out that the temperature at which any hydrate is transformed into a lower hydrate is lowered if foreign substances are added to the aqueous solution with which the two hydrates are in equilibrium at the transition temperature, just in the same manner as the melting point of a pure substance is lowered by foreign admixtures. Consequently we may expect, at one and the same temperature, higher or lower hydrates to crystallise out from a solution according as the mother liquor contains small or large quantities of other soluble substances.

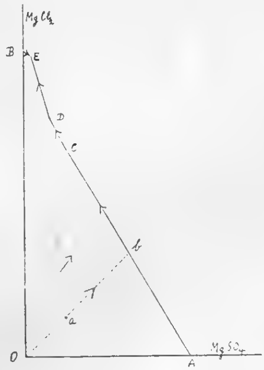

FIG. 3.

The application of these known facts to the crystallisation of a solution containing the sulphate and chloride of magnesium at 25° C. enables us to explain completely the successive changes observed.

Representing, as before, the composition of the saturated solutions of these salts on a system of coordinates, Fig. 3 is obtained. A and B represent the saturated solutions of

$MgSO_4.7H_2O$ and $MgCl_2.6H_2O$ respectively; the point E, which corresponds to the point C in Fig. 1, represents a solution saturated simultaneously with regard to $MgCl_2.6H_2O$ and the hydrate $4MgSO_4.5H_2O$. The broken curve joining A and E has reference to solutions which are saturated with one or other of the hydrates of magnesium sulphate, but not with magnesium chloride.

If a solution containing equivalent quantities of these two salts and represented by the point *a* is evaporated at 25° C., then, as in the cases already considered, separation of salt, viz. $MgSO_4.7H_2O$, will take place when the index point moving along O *a* reaches the curve C A.

As the concentration of the magnesium chloride in the solution increases, we move along the curve A C until at the point C this concentration has attained such a magnitude that the transition temperature $MgSO_4.7H_2O \rightarrow MgSO_4.6H_2O$ has been lowered from 47° C. to 25° C. The separated $MgSO_4.7H_2O$ in contact with the solution is now transformed into $MgSO_4.6H_2O$, and by further evaporation the index point moves along the curve C D, a further quantity of $MgSO_4.6H_2O$ crystallising out. At D the system undergoes a similar change to that which took place at C; $MgSO_4.5H_2O$ crystallises out and the $MgSO_4.6H_2O$ now disappears. Further changes of like character (not indicated in the diagram) are experienced as the magnesium chloride concentration increases, whereby $MgSO_4.4H_2O$ and $MgSO_4.2H_2O$ appear successively. At the point E the hydrate $4MgSO_4.5H_2O$ displaces the dihydrate and the solution then becomes saturated also with regard to $MgCl_2.6H_2O$. These two salts now crystallise out together until the solution completely disappears; the point E represents the crystallisation end point of all solutions containing the sulphate and chloride of magnesium. As before, the arrows indicate the course of the crystallisation for any given solution.

The above crystallisation phenomena may be regarded as typical for solutions containing two salts with a common ion.

The phenomena are much more complex if the solution contains four different ions, as in a solution of the chlorides and sulphates of magnesium and potassium. The four simple salts and their various hydrates, as well as several double salts, may in general crystallise out from such a solution. The course of crystallisation of the solution referred to has been carefully worked out by van 't Hoff, Meyerhoffer and their pupils. The phase rule serves as a safe and sure guiding principle; solubility determinations and measurements of the vapour pressures of solutions supply the data which, when graphically represented in a suitable manner, enable us to follow the various phases of the crystallisation process with almost the same ease as in the simpler cases. The diagram representing the various saturated solutions formed by the system composed of water and the sulphates and chlorides of magnesium and potassium has been tested by a qualitative and quantitative study of the products of isothermal evaporation, and the course of crystallisation is found to agree perfectly with that indicated by the motion of the index point on the diagram. In this short article it is not possible to treat of this more complicated case in detail; suffice it to say that all solutions containing the above-mentioned salts deposit in the last stage of crystallisation a mixture of carnallite, $MgCl_2.6H_2O$ and $4MgSO_4.5H_2O$.

The above sketch gives some idea of the preliminary work in connection with the problem of explaining, on a physico-chemical basis, the formation of the oceanic salt deposits. It indicates the initial stages of the synthetic method pursued by van 't Hoff in his treatment of this highly interesting problem.

H. M. DAWSON.

BOOMERANGS.[1]

BOOMERANGS may be studied for their anthropological interest as examples of primitive art,[2] or for the manner in which they illustrate dynamical principles.[3] But there is extraordinary fascination in making and throwing them, and in watching the remarkable and always graceful curves described in their flight; accordingly, my chief object in the following paper has been to diminish the practical difficulties of the subject by giving some of the results of ten years' experimental acquaintance with it.

The Australian weapons vary enormously in shape and size, while the skill of the natives in throwing them is great in some districts and very small in others. The marvellous flights that were described by former travellers are but rarely seen to-day, and although it is undeniable that many a native can make a boomerang go 80 metres away before returning to his feet, I know of only one trustworthy account of a much more sensational throw.[1] In this the boomerang described five circles in the air, travelling to a distance of about 90 metres from the thrower and rising to a height of 45 metres.

For present purposes it will be convenient to consider two types of implements. The first (Fig. 1) is about 80 cm. in length, measured along the curve, is bent (at B) almost to a right angle, and has the cross section shown in Fig. 2. It is about

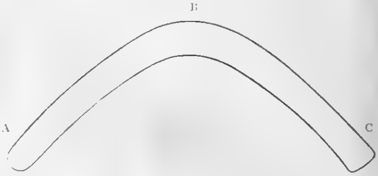

FIG. 2.

FIG. 1.

6·5 cm. wide and 1 cm. thick in the centre at B, and the dimensions of the cross section diminish slightly towards the ends A and C; the weight is about 230 grams. The arms are twisted from the plane ABC after the manner of the sails of a windmill, being rotated through 2° or 3° in the direction of a right-handed screw about the lines BA, BC as axes. This deviation from the plane is subsequently referred to as the "twist," and the peculiarity that, as seen in the cross section of Fig. 2, one face is more rounded than the other, is called the "rounding."

Boomerangs of the second type (Fig. 3) are about 70 cm. long and 7 cm. wide, and have a cross section similar to that of Fig. 2. The "twist" is in the opposite direction, involving a left-handed rotation of about 3°; the axes of rotation are now DE, FE instead of ED, EF.

Returning Flights.—An implement of the first type is held with the more rounded side to the left and the concave edge

FIG. 3.

forwards. It is thrown, with plane vertical, in a horizontal direction and as much rotation as possible is given to it. The plane of rotation does not remain parallel to its original direction, but has an angular velocity (1) about the direction of translation, and (2) about a line in its plane perpendicular to this.

The effect of (2) is that the path curls to the left; while owing to (1) the plane of rotation inclines over to the right (*i.e.* rotates in the direction of the hands of a clock facing the thrower) and its inclination to the vertical becomes comparable with 30° in two seconds. The angular velocity (2) will now imply that the path bends upwards as well as horizontally round to the left.

When the boomerang has described a nearly complete circle its pace has diminished, and it falls to the ground near the thrower. (See Figs. 4, 5, in which projections on a horizontal and on a vertical plane are given; the direction of the axis of rotation is indicated by giving the projections of a line of

[1] This paper is here published by permission of the editors of the *Physikalische Zeitschrift*, for which it was originally written. A German translation has appeared in that journal, and from its publishers the accompanying illustrations have been obtained.

[1] Mr. A. W. Howitt, NATURE, July 20, 1876.

constant length measured along it. The scale of these diagrams is about 1:1000).

The angular velocity (1) is increased by an increase of twist and by an increase of rounding; it also increases when cos θ increases, where θ is the inclination of the plane of rotation to the horizontal. The curling to the left (2) is increased by an increase of twist, or of cos θ, and, in general, by an increase of rounding.

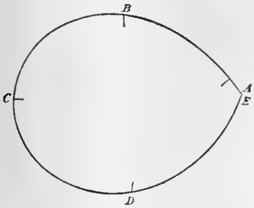

FIG. 4.—Plan.

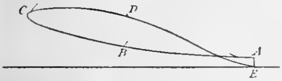

FIG. 5.—Elevation through CA.

If it be desired that the boomerang should describe a second circle in front of the thrower (Figs. 6, 7), it must be thrown much harder, so that when one circle has been described it may still have sufficient forward velocity. When the projectile has described the first circle and is over the thrower's head, the axis of rotation must point in an upward direction in front of him; if it pointed behind him the subsequent path would be behind his back, and a figure of eight (Figs. 8, 9) would become possible. For a path with a second loop in front of the thrower

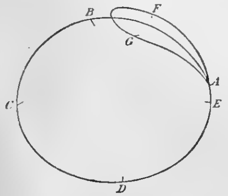

FIG. 6.—Plan.

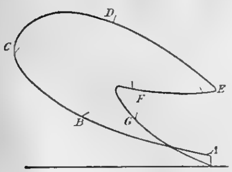

FIG. 7.—Elevation through CE.

he should accordingly choose a boomerang with much twist and much rounding, and throw it with his body leaning over to the left, so that the angle θ between the axis of rotation and the vertical may be slightly in excess of a right angle. The increased twist will mean that the first circle has a smaller circumference and that there will be more pace left after it has been described; and the increased rounding will keep the plane of rotation from becoming horizontal too soon.

For a figure of eight we should require less rounding, or we might give more spin in throwing, and aim a little uphill with θ rather less than a right angle. There are so many elements capable of variation that nothing but experience can teach how to get the best results with any particular boomerang.

The most complex path that the author has succeeded in

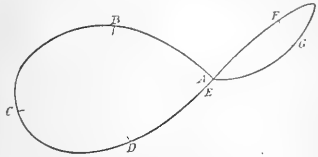

FIG. 8.—Plan.

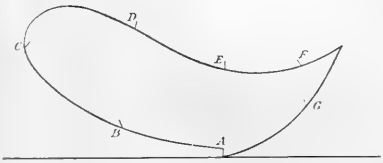

FIG. 9.—Elevation through CAG.

effecting is that of Figs. 10 and 11. But it is certain that these fall far short of what is done by skilful natives of Australia.

If the angle between the arms is increased and the twist and rounding unaltered, the angular velocity (1) is increased, and it becomes easier to make a second loop behind than in front. If the angle exceeds 150°, the angular velocity of the first kind is so large that it is very hard to get a return at all.

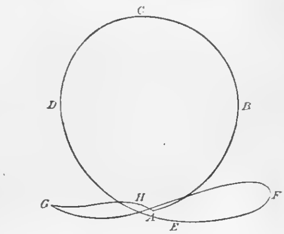

FIG. 10.—Plan.

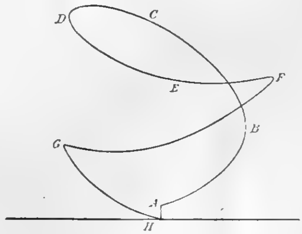

FIG. 11.—Elevation through GF.

When the twist is left-handed and the angle large we have a specimen of the second type (Fig. 3), and it must be thrown with the more rounded side uppermost and the plane of rotation inclined at between 30° and 60° to the horizontal (*i.e.* $30° < \theta < 60°$); the angle of projection (*i.e.* inclination to the horizon of the initial velocity of translation) must be comparable with 45°.

The uphill path is nearly straight until the forward velocity becomes small; the projectile then returns along a track close to that of the ascent (Figs. 12 and 13).

Non-returning flights.—A good boomerang of the second type will travel an immense distance in a nearly straight line if properly thrown. The motion should resemble that of an aëroplane or flying machine; the plane of rotation must remain nearly horizontal though slightly uphill, and the trajectory must be flat. There will thus be an upward pressure of air on the under surface of the implement, and the force of gravity will be counteracted as long as there is sufficient forward velocity. The boomerang is thrown very slightly uphill, the angle of projection not being greater than 12°; the rounded side is uppermost and θ is initially 30°. The plane of rotation soon appears to the thrower to become approximately horizontal, and it remains so during the flight; the projectile rises to a height of about 12m. from the ground and travels in a nearly straight path until its forward velocity is almost exhausted; it then strikes the earth at a distance of about 130 metres from the thrower.

It will be seen that the angular velocity (1) is at first small and positive, and that it subsequently disappears; the angular velocity (2) is small throughout. These results are due to the left-handed twist and the rounding.

Considerable accuracy both in making and in throwing is necessary if the best results are to be obtained. If the plane of rotation slopes downward to one side, the boomerang will slide down in the inclined plane of rotation; thus the path will be bent and materially shortened. The correct relation has to be found between the twist, the rounding, the angle between the arms of the boomerang, the density of its material, and the amounts and directions of its initial linear and angular velocities. An illustration of this is afforded by the first specimen of this type that I have made; it travels further against the wind than with it. In the former case the boomerang keeps quite low, scarcely rising higher than 6 metres, and, being retarded very little by frictional resistance, travels about 125 metres; in the latter case the body spends its energy in running uphill to a height of about 15 metres, and falls to the ground at a distance of about 90 metres.

FIG. 12.—Plan.

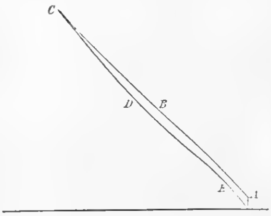

FIG. 13.—Elevation through AC.

It is rather difficult to give sufficient spin to keep the motion stable through a long flight, and I have found it advantageous to wind round the wood about 60 grammes weight of copper wire in three equal portions, of which one is in the middle and one near each end. This materially increases the moment of inertia about the centre of gravity without interfering seriously with other details. I have thrown a loaded boomerang of this type 167 metres, and my range with a spherical ball of half the weight is only 63 metres.

Mode of manufacture.—A block of straight-grained ash about 90 cm. long, 7 cm. (or 7·5 cm.) thick, and of width not less than 7 cm. is taken. The block is soaked in steam, bent to the requisite shape and held in this shape until cool and dry. It is then sawn into strips 1·3 cm. thick. After sufficient time has lapsed for the wood to be seasoned, each strip is trimmed into a boomerang, the most useful tool in general being a spokeshave. It is very important that the outer edge, at any rate in the neighbourhood of the bend, should follow the grain of the wood. When the projectile falls hard upon one end the stress near the centre is very severe, and any point at which the direction of the grain meets the convex edge obliquely is likely to develop a split and ultimately a breakage.

It is better to cut the material to its final twisted shape rather than to impart the twist by another steaming and bending. Considerable care is required in the process, for the removal of a layer of wood a millimetre thick in such a way as to increase or diminish the twist will cause a marked difference in the flight. It will be found to facilitate throwing to cut that end of the boomerang which is held in the hand to the somewhat square form shown at the right hand of Figs. 1 and 3.

There is some difficulty in avoiding warping, for boomerangs are less likely to get broken if thrown when the ground is damp and soft, and under these circumstances the moisture is likely to be absorbed by the wood. It is of great advantage, therefore, to make the surface of the implements very smooth with fine glass-paper and to saturate them with linseed oil. The additional density thereby produced is also of service in that it diminishes the effect of the frictional resistance of the air.

I have used artificially bent oak as a material, but have not found it as heavy or as strong as ash. Oak branches that are naturally bent are not hard to procure, but boomerangs made from them are liable to break at places where there are knots or irregularities in the grain of the wood.

Evolution.—Boomerangs of every variety of shape are still to be found in Australia, and it appears impossible to get direct historical evidence as to the nature of the successive stages of development. But if speculation be allowed, the following series may be suggested.

First we should have a clumsy kind of wooden sword, curved, but without rounding or twist, and with one end roughened to form a handle; when the intended victim was out of reach it would be natural to throw the weapon, and at short ranges it would be extremely effective. Bad workmanship would involve the frequent production of implements of which one side was more rounded than the other, and it would soon be found that these missiles, when thrown with the rounded side uppermost, travelled much further and straighter than the former.

Boomerangs of this character vary in length from 50 to 110 cm., and in weight from 200 grammes to 1250. They are, for the most part, twisted in a manner that seems quite fortuitous, and form the enormous majority of the present native implements. Light specimens with a slight left-handed twist may have a fairly straight trajectory of 100 metres, and may return if aimed much uphill, especially when thrown against a wind. Those which are bent through a large enough angle and happen to be twisted (either by carelessness in manufacture or by subsequent warping [1]) after the manner of a right-handed screw are returning boomerangs of the first type. In many of these the twist is so large as to be conspicuous, and when once the connection between the form and the return flight has been noticed, the process of development is complete.

GILBERT T. WALKER.

THE INTERNATIONAL SEISMOLOGICAL CONFERENCE AT STRASSBURG.

IN 1895 the late Dr. Rebeur-Paschwitz proposed, with the approval of Prof. Milne and other seismologists, to form an international seismological union. Although, unfortunately, he did not live to carry the project into execution, the microseismic survey of the world has since then been actively pushed on by Prof. Milne, the observatories using the Milne horizontal pendulums now numbering about forty. Meanwhile, the project of Rebeur-Paschwitz was taken up by Prof. Gerland, and, thanks to his active exertions, the first international seismological conference was finally held at Strassburg on April 11–13. The total number of the members who attended the conference was thirty-five, as follows:—*Austria-Hungary* (Prof. Belar, Prof. Exner, Prof. von Kövesligethy, Hofrath Konkoly, Prof. Láska, Prof. Schafarzik); *Belgium* (Prof. Langrange); *Denmark* (Lieutenant-Colonel Harboe); *Germany* (Dr. Ebell, Dr. Ehrismann, Prof. Futterer, Prof. Gerland, Prof. Günther, Dr. Hecker, Prof. Helmert, Herr Jaehnike, Prof. Kobold, Geheimrath Lewald, Prof. Leutz, Prof. Rudolph, Dr. Polis, Prof. Schmidt, Dr. Schütt, Prof. Straubel, Dr. Tetens, Prof. Wagner, Prof. Weigand, Prof. Wiechert); *Italy* (Dr. Oddone); *Japan*

[1] This may be illustrated by the fact that when the author first made boomerangs he was only aware of the need for rounding; but the first two specimens that he constructed happened to have right-handed twist and returned admirably.

(Dr. Omori); *Russia* (General Pomerantzeff, Prof. Lewitzky, Dr. Wosnesjenskij); *Switzerland* (Prof. Forel, Prof. Riggenbach). Among these thirty-five members there were sixteen official delegates for the different States, as follows:—*Austria-Hungary*, 1; *Belgium*, 1; *Germany*, 9; *Japan*, 1; *Russia*, 2; *Switzerland*, 2.

The principal object of the conference was the establishment of an international seismological union. After some discussion the *projet* of statutes of an "International Seismological Association," formed principally in imitation of the statutes of the International Catalogue Association and of the International Geodetic Association, was unanimously accepted by the conference, the chief points being as follows:—

§ 1. The object of the Association is the advancement of knowledge of all the seismological problems, which can be solved only by the cooperation of numerous seismological observatories all over the world. As the principal means of attaining this object are proposed:—(1) seismological observations according to fixed plans; (2) experiments on certain important seismological questions; (3) establishment and support of seismological stations in certain countries which need assistance from the Association; (4) organisation of a central bureau for collection and discussion of the reports from various countries.

§ 3. The parts of the Association are:—(1) general meeting; (2) permanent commission; (3) central bureau.

§ 5. The permanent commission consists of the director of the central bureau and of one member from each of the States which compose the Association. . . .

§ 8. Each State must duly communicate to the central bureau, through its local central bureau, the results of seismic observations and experiments.

§ 9. Each State must contribute to the central bureau a certain yearly sum of money, to be fixed in proportion to the number of the inhabitants. The sum thus contributed by the different States is to be appropriated to the following purposes:—(1) publications and administration; (2) remuneration to the general secretary; (3) support of those who work in special important seismological investigations; (4) support of those seismological observatories which are established by the Association. The distribution of the sum into these various items is to be decided by the permanent commission.

As to the seismological observations, experiments and publications in the different States, the latter have a perfect freedom. The choice of the instruments is also left free to each State. The statutes of the Association having been thus adopted by the conference, the further steps for the formation of the Association are now to be taken by the Imperial German Government through diplomatic channels.

As there is still one year or so before the Association can be actually formed, it was proposed by Prof. Helmert to establish a provisionary central bureau and let the latter begin at once the function for the international seismological investigation, under the cooperation of all the members present, who approved the proposal and promised to send in publications and reports. Prof. Forel proposed, in the name of all the non-German members to select the Strassburg Seismological Observatory as the provisionary central bureau, under the direction of Prof. Gerland. This proposal was accepted, the Association being thus provisionally formed. Besides the establishment of the statutes, there were given by Prof. Helmert and others a series of valuable reports and lectures on observational as well as theoretical seismology.

The first international seismological conference proved to be a very satisfactory one. The full minutes of the transactions are expected to be published shortly. F. OMORI.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. R. T. HEWLETT, of the Jenner Institute of Preventive Medicine, has been appointed professor of general pathology and bacteriology at King's College, London.

THE following candidates have passed the D.Sc. examination of the University of London:—Mathematics and Physics, J. Buchanan; Experimental Physics, C. V. Drysdale, W. H. Eccles, P. E. Shaw; Chemistry, T. J. Baker, T. A. Henry, W. H. Hurtley, G. D. Lander, H. R. Le Sueur, S. Smiles.

THE following regulation from the new Calendar of the Imperial University at Kyoto show that the Japanese are encouraging scientific research among University students:—"In June and December every year each student shall report to the director of the College, through his professor, the state and progress of research which he has made in his study of special subject; and the director shall submit such report to the Faculty meeting for examination. When a student has completed the work of research at the University Hall, he shall prepare a record of his career at the University and present it to the president of the University, through his professor." Progress is bound to be made where education is carried on in this spirit.

SCIENTIFIC SERIAL.

Bulletin of the American Mathematical Society, July.—Surfaces whose first and second fundamental forms are the second and first respectively of another surface, by Dr. Eisenhart, was read at the February meeting. The results arrived at are—the ruled surfaces, defined by the equations

$$y + \mu x = \sqrt{1+\mu^2} + C_1\mu + C_1$$
$$z - ix\sqrt{1+\mu^2} = \mu + C_1\sqrt{1+\mu^2} + C_3,$$

are the only surfaces whose first and second fundamental forms can be taken for the second and first fundamental forms of a surface. Further, the second surface is only the first to a translation *près*. And of these surfaces the only real one is the sphere of radius unity—the C's, as usual, are arbitrary constants. References are given to work by Bianchi, Casorati, Monge and Forsyth.—On the groups generated by two operators, by Dr. G. A. Miller, was read at the April meeting. This short note, which gives several references, discusses the theorem, "every group that is generated by two operators of order two is a dihedral rotation group, and every dihedral rotation group is generated by two operators of order two."—Mr. G. Peirce gives a curious approximate construction for π, read at the same meeting. This is as neat a construction as we can remember.—Non-Euclidean geometry is a short notice, by J. L. Coolidge, of a work with this title by Dr. H. P. Manning.—J. K. Whittemore gives an extended abstract of "Vorlesungen über Differential geometrie" (pp. xvi + 659), a translation of Bianchi's work by M. Lukat.—Notes, new publications, tenth annual list of papers (read before the Society, with references to their places of publication), and a full index close the number and the volume.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 20.—"Further Observations on Nova Persei. No. 3." By Sir Norman Lockyer, K.C.B., F.R.S.

In a former paper an account was given of the observations of the Nova, made at Kensington between March 5 and March 25 inclusive. The observations are now brought up to midnight of May 7. Between March 25 and the latter date, estimates of the magnitude of the Nova have been made on thirty-three evenings, visual observations of the spectrum on twenty-five evenings, and photographs of the spectrum on six evenings.

The 10-inch refractor with a McClean spectroscope has generally been used for eye observations. The 6-inch prismatic camera has not been available for photographing the spectrum owing to the faintness of the Nova, but photographs have been secured by Dr. Lockyer with the 30-inch reflector on the nights of March 27, April 1 and 12, and by Mr. Fowler on March 26 and April 4. With the 9-inch prismatic reflector the spectrum was photographed by Mr. Hodgson on March 30, April 1 and 4.

Change of Brightness.—Since March 25 the magnitude of the Nova has been undergoing further periodic variations, and although observations have not been made on every night since that date, owing to unfavourable weather, yet sufficient data have been gathered to enable a general idea of the light changes to be obtained, and the few gaps can be filled up later by other observers who experienced clearer skies on these occasions.

A table is given containing observations for magnitude made from March 26 to May 5 inclusive.

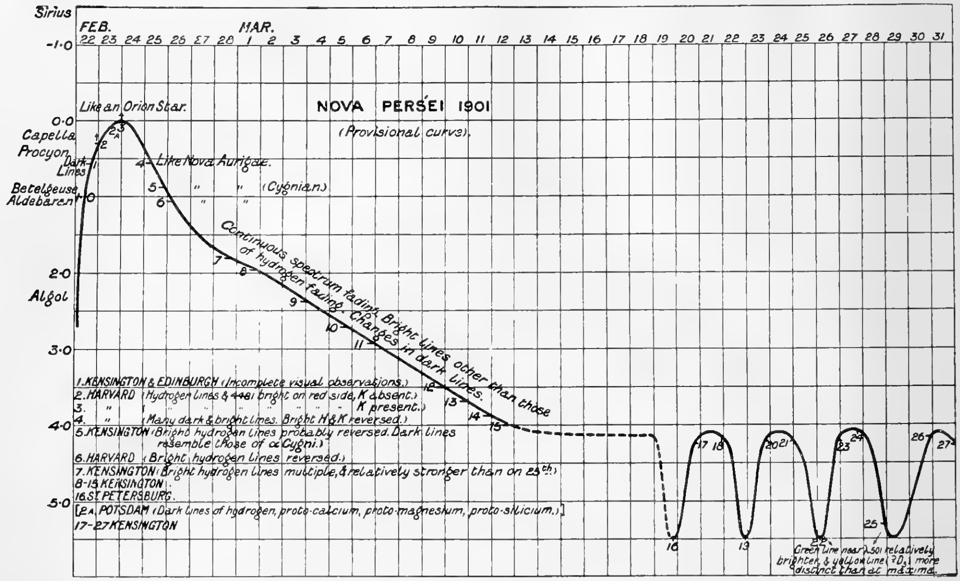
The observations show that the length of the period of variability, reckoning from maximum to maximum, began after March 27 to increase from *three* days to *four* days.

The two following maxima, after that of April 8, occurred on the 13th and 18th, so that the period became still more lengthened, namely to about *five* days. Further observations up to May 5 seem to indicate that the five-day period is shortening.

Another interesting observed fact was that the light of the Nova at the minimum on the 25th was more intense than at the preceding minimum on the 21st, the estimated difference of magnitude at these times being about 4-tenths of a magnitude.

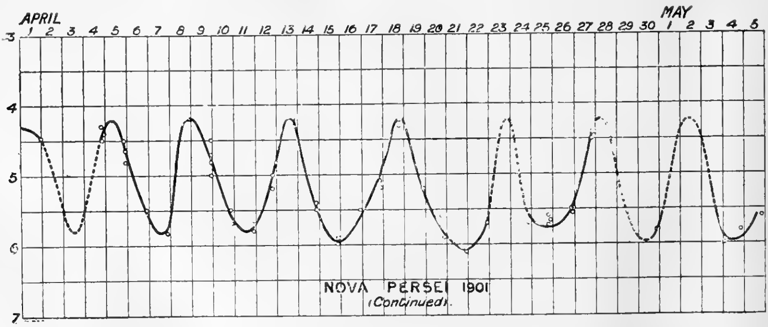
The curve is drawn to satisfy as far as possible all the observations made at Kensington. The dotted portions represent the possible light-curve for those times when no estimates for magnitude could be secured.

In the plates the abscissæ represent the time element and the ordinates that of magnitude.



Colour.—In the first part of the period covered by the later observations, the colour of the Nova has been generally described as yellowish-red, red with a yellow tinge and yellow with a reddish tinge. Since April 25 the colour has been perhaps more red than formerly and sometimes noted as very red.

It is interesting to remark that the colour varies periodically with the change in magnitude. At maximum it is of a distinct yellowish-red hue, but at or near minimum the yellowish tinge disappears and the Nova appears very red.



Unfortunately the increasing twilight and the unfavourable position of the Nova make it very difficult now to determine the magnitudes correctly.

The two plates accompanying this paper illustrate graphically the various fluctuations of the light of the Nova from February 22, when it had not quite attained its maximum brilliancy, to May 5.

The Visual Spectrum.—In the continued observations the C and F lines of hydrogen have always been recorded as "conspicuous," other prominent lines being near λ 447, λ 465 and λ 501 (the last named being sometimes as bright as F or even brighter), and a line in the yellow which recent measures show to be D_3.

The strong lines in the green at λλ 4924, 5019, 5169 and 5317, which occurred in the earlier photographs and which were ascribed to iron, are either absent from the later photographs or appear only as very weak lines.

It has been noted that the lines 447, 501 and D_3 appear to vary with the magnitude of the star, becoming relatively more prominent towards a minimum.

The continuous spectrum has been described throughout as "weak" or "very weak."

On the evening of April 25 Messrs. Fowler and Butler made comparisons of the Nova spectrum with the spectra of hydrogen, helium, and that furnished by an air spark between poles of iron and zinc. For this purpose a Hilger two-prism star spectroscope was used with the 10-inch refractor. The hydrogen line F and the helium line D_3 were found to be sensibly coincident with Nova lines. The middle of the strong green line, previously mentioned as λ 501, practically coincided with the nitrogen line 5005·7, and therefore there is little doubt that it is identical with the chief nebular line λ 5007·6. This line was also compared with the asterium line at λ 5015·7, but was found to be decidedly non-coincident with it, though of sufficient breadth to nearly reach it.

Photographic Spectrum.—In so far as the number and positions of the lines are concerned, the few photographs available for discussion were obtained in the early part of the period dealt with in the present paper (March 26 to May 7), and show a

LIGHT CURVE OF H_β
(30-inch reflector).

spectrum very similar to that of March 25, which was described in detail in the last paper. The chief lines shown in the photographs are Hβ, Hγ, Hδ, Hε and Hζ, together with 4471 and 4650.

Characteristics of Hβ.—In continuation of the series of light curves of Hβ reproduced in the last paper, I give those plotted by Mr. Baxandall from the later photographs.

It will be seen that the line Hβ still shows two maxima of intensity. As recorded in the previous paper, the less refrangible component gave indications of becoming brighter than the more refrangible member. These further photographs indicate that by April 4 the less refrangible had become twice as intense.

"Total Eclipse of the Sun, May 28, 1900.—Account of the Observations made by the Solar Physics Observatory Eclipse Expedition and the Officers and Men of H.M.S. *Theseus* at Santa Pola, Spain." By Sir Norman Lockyer, K.C.B., F.R.S.

The Report gives details as to the erection of coronagraphs, prismatic cameras and other instruments, and of the results obtained by their use during the eclipse, which was observed under very favourable circumstances. Some of the more obvious results have already been stated in a Preliminary Report (*Roy. Soc. Proc.*, vol. lxvii. p. 341), and the following remarks may now be added.

A comparison of the photographs taken with the coronagraph of 16 feet focus with those taken about two hours earlier in America indicates that while some of the prominences changed greatly in appearance in the interval, no changes were detected in the details of the corona.

The spectrum of the chromosphere, as photographed with the prismatic cameras, so greatly resembles that of 1898 that it has not been considered necessary to make a complete reduction of wave-lengths. The prominences visible during totality had comparatively simple spectra, the greatest number of lines recorded being thirty-six.

The heights above the photosphere to which many of the vapours can be traced in the photographs are tabulated and compared with the results obtained in 1898; the two sets of figures are sufficiently accordant, except in the case of the shorter arcs, the value 475 miles derived for the lowest measurable vapours in 1898 being represented in 1900 by two strata, one reaching to 700 miles and the other to 270 miles above the photosphere.

The bright-line spectrum of the corona was decidedly less bright than in 1898, and a much smaller number of rings is seen in the photographs. The three brightest rings are at wavelengths 5303·7, 4231·3 and 3987·0, and it may be noted that these were also the brightest in the eclipses of 1893, 1896 and 1898. The conclusion that the different rings do not originate in the same gas, arrived at from a discussion of the photographs of 1898, has been confirmed.

A drawing is given to illustrate the fact that while the details of the green coronal ring are seen in the inner corona, they have no apparent relation to the positions of the great streamers or prominences. For an investigation of this nature the photographs taken with the prismatic camera of 20 feet focal length are specially valuable.

"On the Mathematical Theory of Errors of Judgment, with Special Reference to the Personal Equation." By Karl Pearson, F.R.S.

EDINBURGH.

Royal Society, July 1.—Prof. Chrystal in the chair.—Dr. Thomas Muir communicated a note on a proposition given by Jacobi in his *De Determinantibus functionalibus*, pointing out that the theorem in question was not so general as might at first reading seem to be implied.—Dr. R. H. Traquair read a paper on the distribution of fossil fishes in the Carboniferous rocks of the Edinburgh district. From a complete classification of the known forms, eighty-four in all, it was shown that the same genera and species were found in all the estuarine deposits, even though these were separated by marine limestones which contained a totally distinct set of fossil remains. There was no evidence of life zones. The forms were persistent and no evolutionary change could be detected. After the Millstone Grit there was no further appearance of the characteristic estuarine forms.—Dr. J. Beard, in a paper on the determination of sex in animal development, argued that the sex of the animal into which a given ovum developed was determined from the very beginning before the act of fertilisation. The argument was supported by an array of facts in embryology, such as the two kinds of oocytes which had been observed in certain animals.

July 15.—The Rev. Prof. Flint in the chair.—The chairman made a suitable reference to the sad loss which the Society and the wider world of science had suffered in the recent death of Prof. Tait, who had been their general secretary for more than twenty years.—The following prizes were then presented: the Gunning Victoria Jubilee prize to Dr. T. D. Anderson for his discoveries of new and variable stars; the Keith prize to Dr. James Burgess, C.I.E., for his paper on the definite integral $\sqrt{\frac{2}{\pi}}\int_0^t \epsilon^{-t^2}dt$ with extended tables of values; and the Makdougall-Brisbane prize to Dr. R. H. Traquair for his report on fossil fishes collected by the Geological Survey in the Upper Silurian rocks of Scotland.—Mr. C. Tweedie communicated a paper on the general form of the involutive one-one quadric transformation in a plane.—In a supplementary report on the fossil fishes from the Silurian rocks of the south of Scotland, Dr. Traquair announced some new anatomical features which he had discovered in these fish remains. Thus in some specimens of Cœlolepidæ, two dark spots were found probably representing the position of the eyes; and in one specimen of *Lasanius problematicus*, vertical angulated lines were seen which might very reasonably be regarded as the remains of body muscle. Nearly perfect specimens of *Ateleaspis tesselata* show this remarkable genus to have close affinity to *Cephalaspis*, having two orbits on the top of the head, a small dorsal fin, and a heterocercal non-bilobate caudal. The cephalic shield is, however, still without cornua.—Mr. Thomas Heath exhibited the photographs of the corona which he had taken during the total eclipse of May 28, 1900. The character of the corona was well marked in all; but from comparison with drawings taken by skilled draughtsmen it appeared that the outlying parts of the corona were not shown in the photographs. This might be due to the brightness of the sky consequent on the eclipse being one of short duration, or to the possible lack of actinic rays in these outlying regions.—Drs. D. Hepburn and D. Waterston read a paper on the true shape, relation and structure of the alimentary viscera of the common porpoise as displayed by the formal method. The animal on which the observations were made was an adult male, captured in fishing nets nearly eight months ago. It was carefully preserved within twenty-four hours of its capture, so that the organs retained their natural shapes and positions, while the various tissues were suitably "fixed" for microscopic examination. The authors have established, among other novel results, the presence of a peritoneal pelvic cavity which was not formerly recorded and which, from its relations to the vertebral column, provides a key to the subdivision of that part formerly called lumbosacral into lumbar and sacral sections. They have also revised the homologies of the multi-chambered stomach and placed them upon a more accurate footing; and similarly as regards the duodenum and intestine. The microscopic structure of the alimentary viscera was likewise examined under favourable conditions. The authors also report the presence of the tape-worm, *Bothriocephalus latus*, not hitherto recorded for marine animals.—Dr. A. T. Masterman communicated a paper on the central plexus of *Cephalodiscus dodecalophus*, M'I.

PARIS.

Academy of Sciences, July 22.—M. Fouqué in the chair.—The president announced to the Academy the death of M. de Lacaze-Duthiers, member of the section of zoology.—Remarks by M. Boussinesq on his work on the analytical theory of heat.—On the acidity of certain animal secretions, by M. Berthelot. In this study of acidity five indicators were employed—methyl orange, dimethylamidoazobenzene, red alizarine-sulphonate, litmus and phenolphthalein. Comparative determinations with these indicators were made of the acidity of the gastric juice, saliva and of urine.—Some observations made with uranium at very low temperatures, by M. Henri Becquerel. It was shown four years ago that between +100° and −20° C. there was no notable variation in the radiation from uranium, and in the present communication the intensity of this radiation is found to be practically constant at temperatures down to that of boiling liquid oxygen.—On the law of pressures in cannon, by M. E. Vallier.—New nebulæ discovered at the Observatory of Paris, by M. G. Bigourdan. Details of the positions and appearance of twenty-three new nebulæ.—On the Hermitian, by M. Léon Autonne. The name "Hermitian" is suggested instead of the "definite form" of Lœwy, and the properties of these functions are summarised.—On an application of potential functions to the theory of elasticity, by MM. Eugène and Francois Cosserat.—On the dielectric cohesion of gases; the influence of the walls, by M. E. Bouty. An experimental study of the disturbances produced by the walls of the vessel containing the gas under examination shows that the critical phenomenon, that is the point at which the discharge commences to take place, is altogether independent of the material of the walls. The action of the latter is indirect, in so far as it modifies in a more or less irregular manner the field in which the gaseous mass stands.—Gratings obtained by the photography of rigorously achromatic fringes, by M. G. Meslin.—On the nature of the X-rays, by M. Jules Semenov. From the experiments described the author concludes that the X-rays represent directions of transmission, by means of the ether, of electrical vibrations. These vibrations communicate themselves to all bodies which they meet in their course. When these bodies are charged with electricity and are protected against discharge by convection, they lose their charge by radiation.—The action of hypophosphorous acid upon acetone, by M. C. Marie. By the interaction of acetone and hypophosphorous acid two new crystallisable acids are obtained, the constitution of which is not yet determined.—The preparation of pure oxide of cerium, by M. Jean Stebba. By the use of electrolysis as a means of oxidation, the method of Wyrouboff and Verneuil is rendered more rapid. The oxide of cerium thus purified from other metals may have a distinct colour, but becomes snow white on completely eliminating the last traces of nitrogen.—The thermal study of the solid hydrates of soda, by M. de Forcrand.—The action of copper hydrate upon solutions of metallic salts, by M. A. Mailhe. With solutions of several metallic chlorides and bromides, copper hydrate gives a mixed basic salt.—The action of silver upon hydrobromic acid and the inverse reaction, by M. Jouniaux. The results obtained were generally parallel with those previously obtained with hydrochloric acid and silver, the value for the heat of reaction calculated from the equilibrium pressures at various temperatures being in practical agreement with the direct determinations of Berthelot.—The oxidation of propylglycol by *Mycoderma aceti*, by M. Andre Kling. The oxidising action of *Mycoderma aceti* upon propylglycol resembles that of the sorbose bacterium, the acetol, $CH_3.CO.CH_2OH$, being produced in both cases.—The action of the pyridine bases upon the tetrahalogen derivatives of benzoquinones, by M. Henri Imbert.—On the chlorides and bromides of the supposed binaphthylene-glycol, by M. R. Fosse.—The action of gaseous ammonia upon the chlorhydrates of fatty amines, by M. Felix Bidet.—On some new vegetable species of Madagascar, by M. E. Drake del Castillo.—Histological researches upon the sporulation of the Schizosaccharomycetes, by M. A. Guilliermond.—On the intracellular diastases of the Amœba, by M. H. Mouton.—Light from the phosphorescent bacilli of the Baltic, by M. J. Tarchanoff.—Electrical stimulation produced by two waves inverse to each other, by M. Georges Weiss.—On the yield of bread from flour, by M. Balland.—The utilisation of wine residues and wines useless through disease as manure, by M. F. Garrigou. The residues left after the distillation of wine, together with large quantities of wine spoilt through disease, are at present discharged into drains and rivers. In this way vast amounts of substances of considerable manurial value are wasted, and in the present paper methods are suggested for utilising these materials.

GREEK PHILOSOPHY AND MODERN CULTURE.

Greek Thinkers; a History of Ancient Philosophy. By Theodor Gomperz, Professor at the University of Vienna. Vol. i. Translated by Laurie Magnus, M.A. Pp. xv + 610. (London: John Murray, 1901.) Price 14*s.* net.

THE study of the history of Greek philosophy requires no defence and, fortunately, little encouragement. Confessedly our intellectual culture can be traced to Greek origin. The subject is so engrossing, and the full comprehension so indispensable, that able minds will be ever ready to consider the problem and give it fuller illustration. How far the questions that provoked discussion in the Greek colonies on the shores of the Mediterranean were intuitive, how far they were acquired, is of small importance in comparison with the manner in which they affect us. In these days, when the spirit of inquiry is active, we may doubt whether we tap the true source of originality by questioning Greek texts and obscure fragments. The spade of the archæologist is proving itself an equally potent factor. The sand-hills and tombs of Egypt have been made to reveal the secrets they have kept so well. Explorations among the ruins of ancient Babylonian or Assyrian cities have unearthed the traces of a highly developed civilisation on the banks of the Nile and the Euphrates which may have operated not less powerfully on the Greek colonists than the Greek philosophy has affected us. It may be that the student of the future, in his anxiety to trace the earliest effects on the human mind, will have to begin his criticism still farther back, but in the absence of any considerable literature we must at present be content to regard our culture as a Greek product.

Among those who have laboured diligently and with effect upon the many problems that exercised the ancient Greek, the researches of Prof. Gomperz will occupy a high place. His book entitled "Greek Thinkers," which appeared in 1896 and is now translated by Mr. Laurie Magnus, is an exceedingly welcome contribution to this subject. This work not only exhibits accuracy of scholarship and critical acumen, but is equally distinguished by lucidity of expression. Perhaps, too, we may say that Prof. Gomperz has been fortunate in his translator. It seems to us that Mr. Magnus has accomplished his part of the work with admirable skill, and that to an English reader the charm of the work is greatly increased by the ease and brightness with which the original thoughts of the German writer are expressed. Prof. Gomperz deserved a good translator. He has done much useful work himself in making his countrymen acquainted with the thoughts and philosophy of J. S. Mill through translations, and it is only fitting that a similar service should be rendered to his monograph.

The main object of Prof. Gomperz's work is, it may be assumed, to show how greatly, and in what particular directions, we are indebted to Greek thought and Greek methods. Of course, as a general principle the effect is admitted, but to trace the connection with any degree of completeness is a matter of no small difficulty. It requires a survey as a whole of the developed intelligence of the Greek mind, an appreciation of the different tendencies of ancient thought, and a very complete knowledge of modern culture. The author thinks it not impossible that in the future we may see an exhaustive universal history of the mind of antiquity. Pending the appearance of such a monumental work, we welcome with gratitude the worthy contribution that is here made to the more general scheme to which it forms an adequate introduction.

In an introductory chapter the author unfolds, as a panorama, the theatre in which all future development was generated. He dwells appreciatively on the effect colonial life and experience exercised on the intelligence and vigour of the nation, fostering, on the one hand, the hardy and courageous disposition of the emigrant; and, on the other, enlarging his horizon and stimulating his ambition by travel and contact with foreign civilisation. It was in the colonies, doubtless from the introduction of the foreign element referred to above, that the greatest intellectual vigour was afterwards found. To them more than to the parent state it was given to steep themselves in intellectual pursuits, and with whom the riddles of the world and of human life were to find a permanent home and to provoke an enduring curiosity.

The author divides his book into three sections—The Beginnings, From Metaphysics to Positive Science, The Age of Enlightenment. Such a division must of necessity be a little arbitrary, suggesting greater breaches of continuity than really existed. Also, at times, it may lead to a little confusion in chronological arrangement, but that is of small importance, since progress never exhibits the uniform onward movement we connect with time. Historical or biographical references when introduced simply play a secondary part as a background, to give effect to the ordered development. As earliest in history, but perhaps more advanced in scientific accuracy, containing, as it did, the accumulated information of the priests of Chaldea and Egypt, the Ionian school comes first under review, and well exhibits the author's general method of treatment. He endeavours to find the principle underlying the original expression, to think as these old philosophers thought, to determine the amount of truth at which each arrived, to give him credit for it, and to compare and contrast it with modern views. In the Ionian school, for instance, we have hitherto, perhaps, too much considered the astronomical teaching, a result of the commanding importance which Thales has acquired, owing to the part the famous eclipse connected with his name has played in scientific chronology. This has introduced a disproportion which is fatal to a general survey. We have forgotten that he also taught that water was the primary element. To have the true measure of the time we have to remember him as a chemist as well as an astronomer. Prof. Gomperz finds in the teaching of this school, underlying the vagueness, two of the corner-stones of modern chemistry—the existence of elements and the indestructibility of matter. At another point the "physiologists" of Ionia actually outstripped the results of modern knowledge. The bold flight of their imagination never rested "till it reached the conception of a single fundamental or primordial matter as the source of material diversity" (p. 46). Prof. Gomperz's comment is, "Here it may almost be said that inexperience was the mother of wisdom." We are inclined to agree with him, though possibly not quite in the sense in which the phrase is used. The scientific teaching of the school seems to have been best at its birth, and rapidly to have deteriorated. But while admitting and appreciating the author's wish to give credit to whatsoever things are true and of good report, difficulties and uncertainties must exist owing to the scarcity of original documents. We get the views of the great thinkers of antiquity filtered through the minds and coloured by the influence of a crowd of disciples, of collectors, of commentators. The author admits that the whole pre-Socratic philosophy is one vast field of ruins. The picture constructed from these scattered mosaic fragments may be very beautiful to look at, but it may not be the same picture that was originally drawn.

We should have liked to follow the author through each school in which he discovers the different tendencies of ancient thought or given some evidence of the discriminating appreciations that have accompanied some time-honoured name. One could linger long over the Eleatics, those pioneers of criticism who sought to rouse mankind from indolence of thought and the disposition to dogmatic slumber. For the paradoxes of Zeno we have always entertained a profound veneration, and the author is kind enough to stir these dry bones and make them live. Some of these he has clothed in a modern dress, but the difficulty does not lie in the dress, and the old problem connected with relative and absolute motion seems as elusive as ever. The tale of the arrow sped from the bow is put into this captious form: "Does an object move in the space in which it is, or in the space in which it is not?" And this seems as good a way as any to put the problem, which does not seem to have been clearly expressed in the original. Similarly with the old, old story of Achilles and the tortoise, to which we believed we could have given a satisfactory answer before reading the author's comments, but now entertain grave doubts. It is a difficult task to frame a paradox which cannot be exploded in less time than it takes to construct it, and the ingenuity of Zeno will be appreciated by those who have attempted to follow him on this thorny path.

The historians and the physicians or medical schools must also be passed over in silence, though it cannot be imagined that in a critical account of Herodotus, for example, there is not much to interest and perhaps something to qualify. The importance of the medical schools is insisted upon, since here exact observation supplied a much needed check to hasty generalisations, and many a forgotten name to whom accident has denied justice appears in this list of worthies, all contributing to build up science as we understand the term. A work of some 600 pages by a German author might be supposed by some to be a very dull work. This would certainly be an error. It is bright and lucid, free from pedantry, and occasionally epigrammatic. Prof. Gomperz promises us two more volumes; we have no doubt but that the interest will be equally well sustained, and we hope he may again meet as pleasant and competent a translator.

MEDICAL AND SURGICAL EXPERIENCES IN THE SOUTH AFRICAN WAR.

A Civilian War Hospital; being an account of the work of the Portland Hospital, and of experience of wounds and sickness in South Africa, 1900, *with a description of the equipment, cost and management of a civilian base hospital in time of war.* By the Professional Staff. Pp. 343. (London: John Murray, 1901.)

THE Portland Hospital was a hospital organised and equipped by voluntary effort in this country for service in South Africa. It was the first of several similar hospitals sent out after the declaration of war in October 1899; but it was not the first voluntary hospital ever attached to a British Army at the front, as the authors suggest in their preface. One well-known hospital, for example, the hospital which is now the British Hospital at Port Said, was originally established as a voluntary hospital for the sick and wounded of the Egyptian Campaigns. The Portland Hospital, however, has the credit of being the first example in this country of a voluntary undertaking on behalf of the sick and wounded being placed entirely in the hands of the military medical authorities for organisation, equipment and management. Formerly the promoters of such undertakings preferred to act independently and, as a matter of fact, to run counter to official medical authority, believing that their usefulness would be in proportion to the extent to which they could over-ride the restrictions imposed by military discipline and control. Continental nations have long ago recognised the folly of this conception, and the Portland Hospital has the merit of having led the way in this country towards a loyal recognition of the necessity of voluntary aid in war becoming an integral part of the military medical organisation. The dedication of the volume to the Principal Medical Officer of the Field Force and to the Officers of the Military Hospital, to which the Portland Hospital was attached, indicates the success of this more modern conception of the value of voluntary aid in war.

The Portland Hospital may, indeed, be regarded as civilian only in name and in the fact that its professional staff consisted of Mr. Anthony Bowlby, Dr. Howard Tooth, Mr. Cuthbert Wallace and Mr. J. E. Calverley, and that the cost of its equipment and maintenance was defrayed from private sources. In other respects it was a distinctly military organisation under an Army medical officer, Surgeon-Major Kilkelly of the Grenadier Guards, and was, in fact, a fifth section of the military establishment known as a general hospital at the base.

The gentlemen named are the authors of this volume, and they have achieved their task admirably. The opening chapters and several voluminous appendices form about one-third of the book and describe the personnel, equipment and interior economy of the hospital. It can scarcely be said that they open up fresh ground or present new facts for consideration. The remaining chapters contain an excellent and valuable record of the medical and surgical work done in the wards of the hospital or in the wards of other hospitals to which the staff of the Portland Hospital had access.

The medical work is recorded in two chapters by Dr. Tooth and Mr. Calverley. The first and more important of these chapters contains an account of the authors' experience of enteric fever and simple continued fever in South Africa. But most of the scientific interest attached to this subject has already been exhausted in a paper by Dr. Tooth which was read and discussed quite recently before the Clinical Society of London, and the chapter is more or less a repetition of that paper. Some interest, however, will be felt in the attitude of the authors towards "simple continued fever," which they express in the statement that a diagnosis of simple continued fever "is little more than a confession of ignorance," but "must be tolerated in the absence of more exact knowledge." In their experience, all such cases were cases of exhaustion, diarrhœa, dysentery, insolation or true enteric fever, and they consider that a medical officer assumes a rather dangerous position in diagnosing a case as "simple continued fever" simply because he does not know what the fever is and does not think it is enteric. All thoughtful physicians will readily acknowledge that there is a general lack of exact knowledge regarding fevers of this kind. In military medical practice these fevers are extremely numerous and seldom fatal, and the term "*febricula*," which was included in former editions of the "Nomenclature of Diseases," issued by the Royal College of Physicians, best indicated the type of fever described and was a less confusing term to use for what was, after all, a symptom rather than a definite disease and for what must necessarily be a provisional rather than a positive diagnosis. It is evident, however, that, in the authors' experience, a large number of these cases were considered to be mild forms of enteric fever. The Board of Medical Officers appointed to inquire into the outbreak of enteric fever in the camps of the United States Army in 1898 came to a similar conclusion; and, if it becomes the fashion to record this type of fever as enteric fever instead of as simple continued fever, we must be prepared for some remarkable variations, statistically, in the incidence and case mortality of the former disease.

The second chapter on medical subjects deals with diarrhœa, dysentery, sunstroke, diseases due to exposure, functional diseases and mental disturbances as experienced in war. It will repay perusal, but can scarcely be described as important. The facts are commonly known and have frequently been described in the medical histories of campaigns. It may, however, be interesting to note that the authors consider diarrhœa and dysentery to be synonymous. "Dysentery," they say, "is diarrhœa writ large,' or, in other words, the two have a common origin." Their reasons for adopting this opinion are not convincing. In fact, no reasons are given other than some vague theories and speculations regarding the probable cause of the well-known diarrhœa of campaigns.

The best feature of the volume from a scientific standpoint is the record of surgical work; and the chapters on this subject, to which nearly one-half of the book is devoted, will cause it to take a high and important place in the literature of military surgery. They are written by Mr. Bowlby and Mr. Cuthbert Wallace, and are characterised, pre-eminently, by thoughtful and careful observation of fact. Hitherto our scientific knowledge of the effects of modern fire-arms has been dependent on experiments, notably those of Prof. Bruns of Tübingen. Mr. Bowlby and Mr. Wallace have at once lifted us from the sphere of experiment into that of actual facts by a series of observations the accuracy and completeness of which are forcibly impressed upon the reader. Briefly, their facts may be regarded as confirming the observations and conclusions of the experimentalists. They had opportunities of observing side by side wounds made by the Mauser and old Martini rifles, both of which were used by the Boers. The modern "perfect" bullet, the bullet with hard mantle and small calibre, causes less shock, both local and general, than the old bullet, and the risk of sepsis is diminished. But the high velocity of the former at short ranges is disastrous and is the cause of the so-called "explosive" effect. The authors' explanation of this is that the energy of the bullet is transmitted to the tissues, and they base this explanation on the symptoms and after-effects of wounds observed by them in which the injury was not confined to the immediate track of the bullet. The tissues beyond were found to be profoundly injured, and these widely-spread effects were largely in proportion to the velocity of the projectile. Thus, in the brain the passage of a bullet at close range is found to result in the disintegration of almost all the cerebral mass, while a certain proportion of patients shot through the brain at extreme ranges made satisfactory recoveries. In bones, too, the effect of high velocity at short ranges is to produce very extensive splintering and pulverisation, whilst at long ranges cancellous bone may be simply perforated and compact bone fractured with but little comminution. These observations completely confirm Bruns' experiments, and they will be quoted as essential facts in future text-books on military surgery.

As regards another well-known phenomenon, fragmentation and alteration in the shape of bullets, the authors' observations lead them to believe that this does not occur, in the case of hard mantled bullets, except as a result of ricochet and impact with hard substances outside the body, a probable explanation which has been overlooked in some recent continental works on the effect of modern fire-arms. Another important observation is that soft-nosed or "sporting" bullets do not "set up" on impact with soft tissues, and only when they hit hard bone. Sportsmen will be inclined to disagree with this, but the authors point out that the hide of big game is compact enough to cause "setting up" of a soft-nosed bullet, whereas the human skin is not.

These are only a few of many interesting and important observations made in the chapters on the surgical work of the hospital. In pages devoted to bullet wounds of blood-vessels, nerves, joints, head and abdomen there are points of special interest and value, which throw a flood of light on many questions connected with the surgical work of modern wars, and which every surgeon, certainly every military surgeon, should study.

The volume is profusely illustrated by photographs, including some skiagraphs, which add greatly to the interest and value of the book. It also contains a useful index.

W. G. M.

A CATALOGUE OF PALÆARCTIC LEPIDOPTERA.

Catalog der Lepidopteren des Palaearctischen Faunengebietes. I Theil: Famil. Papilionidæ—Hepialidæ. Von Dr. O. Staudinger und Dr. H. Rebel. Pp. xxxii + 411; portrait; II Theil: Famil. Pyralidæ—Micropterygidæ. Von Dr. H. Rebel. Pp. 368. 8vo. (Berlin: R. Friedländer und Sohn, Mai 1901.) Price Mk. 15 (paper); Mk. 16 (cloth).

THE publication of the third edition of Staudinger and Wocke's Catalogue of Palæarctic Lepidoptera is an event of considerable importance. In the earlier part of the last century, the catalogues of European Lepidoptera most in use were those of Boisduval, who published the first edition of his "Index Methodicus," including Papilio, Sphinx, Bombyx and Noctua (in the Linnean sense), in 1829; and the second edition, to which the Geometridæ were added, in 1840. The latter edition included 1941 species, among which are enumerated the few species then known from the Caucasus and Siberia; for Continental entomologists have always treated the insects of the adjacent countries as virtually forming part of the European fauna. In 1844 Duponchel published a more elaborate "Catalogue Méthodique des Lépidoptères d'Europe" (pp. xxx + 523), including the whole Order.

Between 1843 and 1851 the German entomologist, Heydenreich, published three editions of his "Systematisches Verzeichniss der europäischen Schmetterlinge," the last of which extends to 130 pages, double columns; and the first edition of the "Catalog der Lepidopteren Europa's und der angrenzenden Länder, I. Macrolepidoptera, bearbeitet von Dr. O. Staudinger; II. Microlepidoptera, bearbeitet von Dr. M. Wocke" was issued in a nearly similar form to Heydenreich's. It was published in Dresden in September 1861, and includes pp. xvi + 192 (double columns). This catalogue includes 5250 species in all; and the 1941 species of Macrolepidoptera enumerated by Boisduval in 1840 proved to have increased, in little more than twenty years, to 2583. This catalogue was very complete and carefully compiled (especially in its earlier portion, for Dr. Wocke's work is far inferior to Dr. Staudinger's), and it at once took its place as the standard catalogue of European Lepidoptera. This edition included no localities; but those species which did not occur within the geographical limits of Europe were marked with an asterisk. The title pages and preface were duplicated in French and German.

In another ten years (January 1871) a second and greatly improved edition was issued (pp. xxxviii + 426)—this time in single pages, except that a side column is devoted to full localities of each species and variety. The number of species enumerated had now risen to 2849 Macrolepidoptera and 3213 Microlepidoptera, or 6062 in all. The catalogue includes the species of Europe, North Africa, Asia Minor, Transcaucasia, Siberia as far as the Amur, and Greenland and Labrador, but is yet very far from including the whole of the Palæarctic region; for Dr. Sclater's epoch-making paper on the geographical distribution of the class Aves was only published in vol. ii. of the *Journal* of the Linnean Society in 1858, and did not attract the attention of entomologists till some years afterwards.

This second edition of 1871 has long been out of print, and for many years Dr. Staudinger had been making preparations for a new edition, to include the bulk of the Palæarctic fauna, a work rendered much more arduous by the immense increase in entomological literature, as well as by the large number of new species discovered during the last thirty years. The work has, however, been finally carried to a successful conclusion by Dr. Rebel, Dr. Staudinger's old colleague, Dr. Wocke, having predeceased him by some years.

The present edition includes a portrait of the late Dr. Staudinger, a German preface by Dr. Rebel, chiefly relating to the preparation of the work, a tolerably full bibliography and list of geographical names, and a sketch of the system adopted, which, we may say, without being absolutely revolutionary, exhibits profound modifications from that used in the earlier editions of the catalogue. Then follows the bulk of the work, comprising (allowing for supplementary additions) 4756 Macrolepidoptera and 4963 Microlepidoptera, or 9719 species in all.

The present catalogue now includes the Lepidoptera of the greater part of the Palæarctic region and the circumpolar region. Among the most important additions to the districts included in the second edition are the Nile Delta to Cairo; Asia, to the northern frontiers of Thibet, and the lower course of the Hoang Ho to the Chingan Mountains; North Manchuria and the whole district of the Ussuri; North Japan (not southern Japan, in which case Corea and the greater part of China must also have been included); Central Asia, Palestine, Persia, &c. A few varieties of species noticed, which occur beyond these limits, have also been included. These are marked with an asterisk; but we regret that the strictly European species are not, as in previous editions, indicated by the presence or absence of any special mark.

Dr. Rebel appears to have done his work very completely, English and other works published in 1900 being quoted in the addenda. We notice references to pp. 552 and 581 of the *Transactions* of the Entomological Society of London for that year.

The two parts of the work are separately paged and have separate title-pages, but are bound in one volume. The indices are very bulky, occupying no less than 102 pages of the second volume; the index of families and genera fills sixteen pages, in double columns; and the index of species, varieties, aberrations and synonyms fills no less than 86 pages of very small type in triple columns.

We need hardly say that the work before us will be an absolutely indispensable handbook to all Lepidopterists who are working at any part of the Palæarctic fauna for many years to come—probably till it is superseded by a new edition. At the same time, we cannot expect any book to be absolutely complete or faultless. To have made the bibliography complete would have been impracticable, and we notice that some books not included in it are quoted in the catalogue. Again, we notice the omission of various varietal names; but some entomologists consider that the naming of varieties has been carried much too far of late years, both in Lepidoptera and in

Coleoptera. A certain amount of discretion as to what to include and what to omit, as well as in the selection of synonyms, must be conceded to every cataloguer. A few misprints are corrected at the end of the book, and we have noticed others; but they are not of a character to interfere in any way with the usefulness of the book, and an occasional misprint is absolutely unavoidable in a work of such an extent, and including such a vast amount of minute detail. W. F. K.

AN EPITOME OF MODERN CHEMISTRY.

Modern Chemistry. Part i. *Theoretical Chemistry.* Pp. 126; Part ii. *Systematic Chemistry.* Pp. 203. By William Ramsay, D.Sc. The Temple Primers. (London: J. M. Dent and Co., 1900.) Price 1*s.* each.

GIVERS of inexpensive Christmas remembrances—something more than a card and less than a present—have made us very familiar with the small volumes of the Temple series, and at a first glance the title pages of the two books before us seem to promise selections from Epictetus or De Quincey rather than an exposition of modern chemistry by a living authority. In the first of the volumes Prof. Ramsay has given an extremely condensed account of the present state of chemical theory, and in the second an equally condensed account of systematic chemistry. Both books bear the marks of freshness and originality, and, it must be added, both produce a certain feeling of breathlessness. They are eminently readable to a chemist, and extremely interesting as displaying a sort of camera obscura picture of the territory of chemistry as it is presented in the mind of one of the most active, most unconservative and most distinguished of contemporary workers.

The question that forces itself most persistently upon a critic is—for what class of readers are these books intended? They are called primers, and the present writer, wishing to fortify his opinion that a primer was essentially a book for beginners, has found, on reference to a dictionary, that a primer is "a small elementary book for religious instruction or for teaching children to read." He has, further, taken the trouble to put one of these primers into the hands, not of a child, but of a friend of more mature years and not wholly strange to scientific notions, with the request that he would see what he could make of it. The answer came quickly and in unmistakable terms. The word primer has really no justification in connection with these books; they are in no wise suited to beginners. To those who are working in one little corner of chemistry with their eyes averted from all that is going on elsewhere, and to workers in other sciences who at one time have known a fair amount of chemistry, Prof. Ramsay's survey may be just what they have been wanting. Considering the limits of space imposed, he has given a wonderfully complete and connected account of the state of modern chemistry. The book on theoretical chemistry is naturally the more readable of the two, and it forms a more continuous story. The systematic chemistry exhibits and classifies the facts of chemistry in a way which is striking and interesting and well suited for retrospective purposes. Stress must be laid upon this last qualification, for it is to be feared that a reader who had not already a very good grounding of chemistry would be unable to make any headway in the subject if he started along the lines on which Prof. Ramsay has achieved his formidable task.

To those who wish to refresh their knowledge of chemistry or to look at it from a new point of view, and to those who wish to gain some idea of the very important changes which have been affecting the whole science during the past fifteen years, Prof. Ramsay's little book may be warmly recommended. Such readers will carry away some knowledge at least of "phases," electro affinity, the later developments of stereochemistry and many other innovations; and they will see, with mixed feelings perhaps, how the modern electrochemical theory is changing the whole language of the science.

A. S.

OUR BOOK SHELF.

Essays, Descriptive and Biographical. By Grace, Lady Prestwich. With a memoir by her sister, Louisa E. Milne. Pp. 266. (Edinburgh and London: William Blackwood and Sons, 1901.) Price 10*s.* 6*d.*

LADY PRESTWICH, who survived her husband, Sir Joseph Prestwich, but little more than three years, died in 1899 at the age of sixty-six. They were married in 1870, and settled at Shoreham, near Sevenoaks, in the charming house of Darent-Hulme, built by Prestwich. While he was professor of geology at Oxford, many months in each year were spent in that ancient home of learning, and there Prestwich was constantly assisted by his wife in the preparation, not only of his standard work on geology, but also of his lectures, diagrams and geological papers. Herself an authoress, she had exhibited considerable literary ability in her two novels, "The Harbour Bar" and "Enga," and in a number of essays printed in *Good Words*, *Blackwood's Magazine*, the *Leisure Hour*, &c. Some of these are here reprinted. There are "Recollections of Boucher de Perthes," being the history of the discovery of Palæolithic implements; "Evenings with Madame Mohl," or reminiscences of a Paris salon; "An Evening with Mrs. Somerville"; some account of the parallel roads of Glen Roy, and essays on physiography, all pleasantly and instructively written. One article not previously published is on the old almshouse of Ewelme, and another is on the Findhorn, especially attractive to Lady Prestwich, as her earliest home was in Morayshire, on the banks of this, perhaps the grandest of Scottish rivers.

In the memoir, which has been attractively written by Miss Louisa Milne, we have the record of the life of a good and highly cultured woman, a life comparatively uneventful, it is true, but the record will be found full of interest to those who had the privilege of knowing Lady Prestwich, while others who peruse this volume will derive instruction, always pleasantly conveyed, and make acquaintance with a charming personality. Amid her many occupations, Lady Prestwich found time for much active benevolence and for work relating to the higher education and employment of women. In her younger days she travelled much with her uncle, Dr. Hugh Falconer, and reminiscences of these journeys are extracted from her diary. An interesting essay on "our white deal box" tells the story of the trouble they had in passing this box through the custom-house at Naples, as it contained mysterious plaster casts of the head and bones of a rhinoceros. Even the letters F.R.S. after Falconer's name puzzled the officials. "Royal Society sounded well, but how was the word Fellow to be rendered in French or Italian? I had to be careful, since it could be interpreted in more than one sense. A little heedlessness on my part might bring on my uncle the same sentence as was passed in another Italian town on a Cambridge don who had 'Senior Wrangler' inscribed on his passport. The police translated it as 'inveterate brawler'! and he was in consequence denied permission to travel, and was detained eight days before being allowed to proceed."

Chemical Lecture Experiments. By Francis Gano Benedict, Ph.D. Pp. xiv+436. (New York: The Macmillan Company, 1901.)

THE days of that ancient bugbear, the "Guide to Knowledge," containing in the form of questions and answers a concise *résumé* of all "the scientific facts that a well-educated boy or girl should have learnt," are fast coming to an end. Dr. Benedict has struck another blow at them in issuing his manual of "Chemical Lecture Experiments." The aim of the book is to furnish teachers with a set of trustworthy experiments which can be carried out with ordinary, simple apparatus, all others being rigorously excluded.

It is unnecessary nowadays to comment on the value of experimental demonstrations in a lecture-room, and, as the author points out in his preface, it is unwise to neglect them and trust entirely to laboratory exercises. The latter, "however great their influence in developing the experimental side of teaching the science, have their limitations experimentally and educationally, and cannot supplant the experimental lecture, for it is in the lecture, and there only, where each experiment stands out clearly defined and unattended by the distractions necessarily accompanying laboratory exercises, that the first accurate observations of chemical phenomena can be made by students."

The testimony and example of such illustrious teachers as Bunsen, Liebig, Victor Meyer, and in our own day of Ostwald, Fischer and Moissan, are arguments strong enough to overcome any objections, and Dr. Benedict is to be congratulated on his efforts to lighten the task of the overworked and much-abused teacher. Although he may not be able to lay claim to any great originality, the field having already been pioneered by Arendt and Heumann and Newth, he has succeeded in collecting a good series of experiments to illustrate an elementary course of inorganic chemistry, which, by reason of the careful descriptions and clear diagrams, will commend themselves to all who are conducting classes with only a very limited supply of apparatus and means.

A Manual of Laboratory Physics. By H. M. Tory, M.A., and F. H. Pitcher, M.Sc. Pp. ix + 284. (New York: John Wiley and Sons, 1901.)

THE rapid extension of the study of practical physics in recent years is shown by the number of books which have been published lately dealing with this subject, but we cannot say that much originality has been shown either in the mode of treatment or in subject matter. The exercises are generally those with which teachers are well acquainted. In this book the object of the authors has been to compile notes which will save the demonstrator as much separate explanation as possible. It will therefore be of use in laboratories where funds do not permit many assistant demonstrators to be employed.

The book deals with the whole of physics except mechanics and hydrostatics. Each exercise is divided into the following sections: References to books dealing with the special phenomenon; apparatus required; theory of the experiment; practical directions; example; and a blank to be filled in by the student.

There are a few points about which a word or two may be said. We should have liked to have seen more stress laid on the necessity of students recording the precise nature of the quantities in terms of which their measurements are made. It is not well for them, for example, to see the velocity of sound expressed as 34230 cm. Some of the diagrams leave much to be desired; that of the trace left by a tuning-fork on a falling smoked plate is strangely irregular. The present writer has not tried this experiment under the conditions shown in the figure, but he would expect to get a more intelligible record. The trace obtained with the pendulum-chronograph is also very unlike what we should expect.

The simple wire bridge for measuring resistances is described as the B.A. bridge. We were under the impression that the particular modification introduced by the committee of the British Association was that in which arrangements were made for using Carey Foster's system of interchanging a pair of nearly equal coils.

A good deal of attention is given to the testing and calibration of ammeters. This is very useful to those students going on to the engineering side of physics.

It may be of interest to consider the directions in which a development of practical physics teaching may be expected. There seem to be two ways open for this to take place. The first is to make the laboratory exercises follow precisely the course of lectures, so that the student performs experiments which illustrate what he has been taught in the lecture. This is the rational way of coordinating the teaching and practical work, but it is open to the objection that a much larger stock of apparatus is required. The second direction of development is to allow the student to make the greater part of his apparatus, and this forms the best training for research. Such books as Prof. Threlfall's "Laboratory Arts" is a step in the latter direction, whilst some of the modern more elementary text-books are on the former plan.

In another way this book is of interest to us, as it shows the standard of work reached in the elementary classes in the McGill University, where the physical laboratory is one of the finest and best fitted departments. So far as one can judge, the standard is much the same as in similar classes at home. S. S.

The Story of Wild Flowers. By Rev. Prof. G. Henslow, M.A., F.L.S., F.G.S., &c. With forty-six figures in text. Pp. viii+249. (London: George Newnes, Ltd., 1901.) Price 1*s*.

THIS interesting little book contains much more than its title might seem to imply, since it treats, not only of flowers, but also of the lives and forms of flowering plants, their distribution and evolution. Though both readable and instructive, this booklet loses much in value as a trustworthy popular introduction to botany because its author has elected to saturate it with the extreme form of neo-Lamarckism, of which he is so fervid and, in this country, so isolated an advocate. Much of Prof. Henslow's treatment of the subject is refreshing, and in this respect the chapters on stipules and on vegetative sports, as well as the occasional references to horticultural operations, are especially worthy of note. The author's views on morphology do not, however, always accord with modern opinions; he writes, for instance, "The leaf usually consists of two parts, the leaf-stalk . . . and the blade . . ." (p. 64). "The homology of bracts is various. They may be *stipular* as in Magnolias, more generally are *petiolar* as in Hellebore . . ." (p. 97). Other not generally accepted views are those expressed in reference to the cause of the rosette-form of "high Alpine plants" (p. 103), the significance of circumnutation in twiners (p. 100), and the object of movements of leaves (p. 104). But most open to criticism are the explanations offered of the origin of certain structural and habitual features by the inheritance of the effects of repeated stimuli. In the second volume, on non-European flowering plants, which the author half promises, it is to be hoped that attention will be directed rather to the well-tested facts of evolution than to mere hypotheses as to the precise causes of evolution in special cases.

LETTERS TO THE EDITOR.

Hair on the Digits of Man.

THE distribution of hair on the dorsal surfaces of the digits in man, anthropoid apes and monkeys, is referred to by Romanes in "Darwin and after Darwin," but its significance seems to be overlooked. I would venture to suggest that these facts bear a Lamarckian, and only a Lamarckian, interpretation. It is clear that if acquired characters can be inherited through use, habit or environment, the loss of certain characters through habit and the like may also be inherited, and the development of characters on the one hand and the decay of characters on the other will be sufficient to prove that Weismann's great rule is not absolute. Use-inheritance and disuse-inheritance ought both to be capable of proof. It may be difficult, or impossible, to *prove* the greater cases, such as the long cervical vertebræ of the giraffe and the great horns of the elk, and indeed most of the instances brought forward by Herbert Spencer, Eimer and Cunningham. These may lie open to a selectionist interpretation. But it becomes well-nigh impossible to carry such an interpretation into the trifling biological characters to which I would briefly refer.

In man, hair is entirely wanting on the ungual phalanges of his hand and foot, very rare on the middle phalanges of either foot or hand, and always present more or less on the first row of phalanges in both foot and hand. On the middle phalanges, where it occasionally occurs, it is best looked for in early childhood, when the hair is more strongly developed than in infancy, and when it has not yet disappeared through secondary causes. I have just examined the case of a child of four and a half years old with marked hair on the middle phalanges of the four digits on the hand, and on the second, third and fourth digits of the foot, and with *none* on the fifth digit, except on the first phalanx. It is worthy of remark here that many of the facts of hair-direction, being somewhat fugitive in character, are best studied in the human subject in childhood.

Assuming that man is the child of the monkey, it follows that his ancestors possessed at one time hair on all the phalanges of both foot and hand, as is the case in all the existing monkeys of the Old World and New World that I have been able to examine; though a Chacma baboon at the London Zoological Gardens shows abundant hair on all the phalanges of the foot, and on the middle and ungual phalanges of the hand either no hair or the small amount that is present very much worn down. In the few anthropoid apes that I have been able to examine, the chimpanzee resembles the human subject in this character, and the young orang at the Zoological Gardens possesses hair like that of the lower monkeys, *i.e.* on all the phalanges of foot and hand, though on the two terminal phalanges of the hand the hair is worn down and quite bristly, even though the animal is still young.

Broadly speaking, these facts are congenital and must be acquired, either through heredity, variation and selection, or as the result of habit, such as that of friction, acting through numerous ancestors in a similar direction. We need only bear in mind how much greater is the exposure to friction, in the movements of the hand of man, of the ungual and middle phalanges than that of the first phalanx to see that the conclusion as to the Lamarckian view here put forward is difficult to resist.

This very small point seems to be more worth considering than its intrinsic importance would warrant, in consequence of the way in which a disputed biological doctrine, such as that of Weismann, is being exploited in a somewhat serious matter. It is enough to quote W. K. Brooks, of America, and Prof. J. Arthur Thomson, of Aberdeen, in support of the statement that Weismann's doctrine is "not proven." I refer to the long and somewhat heated discussion which has taken place recently in the columns of the *Lancet* on the subject of "Legislation against National Intemperance." The greater vigour of assertion and multitude of words, if not greater logic, rests with the advocates of the view that alcoholism is a selective influence of value in the evolution of man and ought not to be interfered with by legislation. The reasons for this startling contention are numerous, but their justification rests ultimately on the doctrine of Weismann carried to the bitter end, viz. that acquired characters are not inherited. I submit that if it can be shown that no other than a Lamarckian interpretation of certain small phenomena is possible, something may be done towards making a breach in a somewhat dangerous citadel. WALTER KIDD.

July.

Pseudoscopic Vision without a Pseudoscope: A New Optical Illusion.

A METHOD of securing an illusion of binocular vision wholly without instrumental aid occurred to me recently, which is interesting in connection with the study of pseudoscopic vision. It is fully as startling as any of the results obtained with the lenticular pseudoscope, which I showed at the Royal Institution in February, 1900, and which I shall speak of presently, and, requiring the aid of no optical instrument, is much more impressive.

A lead pencil is held point-up an inch or two in front of a wire window screen, with a sky background. If the eyes are converged upon the pencil point, the wire gauze becomes somewhat blurred, and of course doubled. Inasmuch, however, as the gauze has a regularly recurring pattern, the two images can be united, and with a little effort the eyes can be accommodated for distinct vision of the combined images of the mesh. To accommodate for a greater distance than the point upon which the eyes are converged requires practice, but the trick is very much easier in this case than in the case of viewing stereoscopic pictures without a stereoscope.

As soon as accommodation is secured, the mesh becomes perfectly sharp and appears to lie nearly in the plane of the pencil point, which still appears single and perfectly sharp. If now the pencil is moved away from the eyes which are to be kept fixed on the screen, it *passes through the mesh and becomes doubled*, the distance between the images increasing until the point brings up against the screen. If now the pencil be removed it will be found that the sharp images of the combined images of the gauze persists, even though the eyes be moved nearer to, or farther away from, the screen. Bring the eyes up to within six or eight inches of the plane in which the mesh appears to lie and attempt to touch it with the finger. *It is not there:* the finger falls upon empty space, the screen being in reality a couple of inches further off. This is by all means the most startling illusion that I have ever seen, for we apparently see something occupying a perfectly definite position in space before our eyes, and yet if we attempt to put our finger on it we find that there is nothing there.

It is best to begin by holding the pencil an inch or less in front of the screen. As the eyes become accustomed to the unusual accommodation, the distance can be increased. I have succeeded in bringing up the apparent plane of the mesh, five or six inches, but this requires as great a control over the eyes as is necessary in viewing stereoscopic pictures without an instrument.

The pseudoscope, which I have alluded to above, I have described in *Science* (about November, 1899), but inasmuch as the description of it which I sent to NATURE, the editor informs me, was never received, a brief account of it may not be out of place. Two lenses of about three inches focus are mounted in front of a pair of stereoscope lenses in such a way that the real inverted images formed by them in space can be combined by the stereoscope. The lenses should be mounted in slide tubes attached to the frame of the stereoscope, so that proper focussing can be accomplished. This instrument has been named the lenticular pseudoscope by the psychologists, and gives results far superior to those obtained by the Wheatstone and other forms of mirror pseudoscopes. Viewed through the instrument, a hollow bowl appears as a beautifully convex dome, and if a marble be dropped into it we witness the astounding phenomenon of a ball rolling up hill, crossing the top, descending part way down the other side and then returning to the summit, in defiance of the law of gravitation.

Johns Hopkins University. R. W. WOOD.

Markings on Jupiter.

THERE is a large, dark spot on the southern side of the S. equatorial belt (and nearly in same latitude as the red spot) which on July 24 was preceded by a number of small black dots 5° to 10° apart, according to the observations of Dr. Kibbler, of Stamford Hill, who appears to have been the first, or one of the first, to discern these interesting markings. The largest spot seems to be drifting westwards, relatively to the zero meridian (System II.) of Mr. Crommelin's ephemerides, at the same rate as the S. temperate zone of Jupiter, viz. 16 degrees per month. On August 3 I observed the spot in transit at 8h. 56m., hence its longitude was 232°·8. If the westerly drift of the object is continued and its existence sufficiently prolonged, it will arrive at conjunction with the following end of the red spot in July, 1902, the longitude of the latter being about 46°. This value has shown little variation during the last twelve months.

The new marking deserves special notice from the fact that a conspicuous spot appeared in about the same latitude in the summer of 1889 and formed the subject of an interesting paper by Mr. A. S. Williams in the *Monthly Notices* for June, 1890. This spot, when its more rapid motion enabled it to overtake the red spot, was diverted southwards and its material flowed along the southern edge of the ellipse, afterwards drifting further west, freeing itself from the red spot, and finally appearing as a well-defined red streak or short belt. The present disturbance may indicate a recurrence of the phenomena of twelve years ago, and it is desirable that its future developments be closely watched. The chief spot will be central at about the following times:—

MEASUREMENTS OF SOLAR RADIATION.[1]

IT is impossible within the limits of a short notice to give any detailed description of Prof. S. P. Langley's great work, contained in his first volume of the "Annals of the Astrophysical Laboratory of the Smithsonian Institution." It is an account of his experiments with the bolometer, begun on Mount Whitney in 1881 and continued for eighteen years, first at the Allegheny Observatory and, since 1890, at the Smithsonian Institution at Washington. The volume before us deals with this last period; the results of the earlier period are contained in the Report of the Mount Whitney Expedition, published as one of the professional papers of the U.S. Signal Service Department and elsewhere. Striking as these were, their interest and importance is entirely eclipsed by the new work.

Those who were fortunate enough to be at the Oxford meeting of the British Association in 1894 heard from Prof. Langley himself an account of his researches up to that date. The details on which that account was based are given in the new volume, together with the results of a completely new set of measurements, made in 1897-98.

Probably only the few who have used the bolometer can fully appreciate its difficulties. The principle of the research is simple. A spectrum is formed by suitable means and allowed to fall on the bolometer, a very narrow strip of blackened platinum placed parallel to the lines of the spectrum; this strip forms one of the arms of a Wheatstone's bridge, the other arms being a similar strip and two equal bridge coils. A screen is interposed between the spectrum and the bolometer, and the bridge adjusted until the galvanometer is undeflected. On removing the screen the bolometer strip is heated by that part of the spectrum which falls on it; its resistance is changed and, assuming the battery current to remain constant, the deflection of the galvanometer spot is a measure of the change of resistance of the strip and hence of the energy which it absorbs from the spectrum.

The spectrum is then made to pass slowly across the strip; by noting the corresponding deflections of the galvanometer, a map can be drawn showing the distribution of energy in the spectrum. In a region of a great energy the deflection is large, but as an absorption band crosses the strip it falls towards zero. When it is stated that a variation in the temperature of the strip of less than one millionth of a degree affects the galvanometer appreciably, some of the difficulties become apparent; the very slightest changes in temperature of any part of the electrical system produce effects in the galvanometer which mask the effects it is sought to observe.

In early days the observations were made by eye. The circle carrying the prism or grating which formed the spectrum was set and its position noted; then the screen was removed and the galvanometer deflection read. The circle was then moved and the operations repeated. In 1891-92 the apparatus was made autographic; the circle was turned uniformly by means of a clock, thus the spectrum crossed the bolometer strip at a uniform rate, while the spot of light from the bolometer mirror was focussed on to a sheet of photographic paper, which was made to move vertically at a rate bearing a fixed ratio to that of the circle. On developing the sheet a bolograph was formed, a curve in which the coordinate of any point measured parallel to the direction of motion of the sheet determines the portions of the spectrum to which the point corresponds, while the coordinate measured at right angles to the direction of motion gives the energy received by the strip from that portion of the spectrum. Peaks on the curve correspond to maxima of radiation, depressions to absorption bands or minima of radiation.

A very large number of these bolographs were taken, and the work contains numerous examples. The same general features recur in them, though of course there are small variations from day to day, some of which are real, depending on the weather, while others are accidental. A very full account is given of the steps taken to determine which of the depressions were real, *i.e.* actually due to absorption lines in the solar spectrum, and which were accidental, and of the method of measuring the twenty-one bolographs selected for final examination and record.

Full tables of the wave-lengths of the lines observed and of their relative intensities are given, and the whole is summed up in the normal map of the solar spectrum, which will be found at p. 200.

The general effect is shown in Plate xx., which gives the infra-red spectrum of a 60° rock-salt prism from the observations of 1898, showing both the bolographs, or energy curves, and the line spectrum. The bolographs are, it must be remembered, continuous curves having peaks and depressions; the method adopted for obtaining photographically from these a diagram of a line spectrum as usually drawn is explained on p. 73 thus:—

"One method of obtaining a linear spectrum consists in blacking in all of the plate below the photographic plate and then photographing this through a combination of a spherical and cylindrical lens, which draws the blacked-in portion out into regions of greater or lesser shade according to the linear depth of the blacked-in portion."

". . . In the original curve the greatest elevations represent regions of the greatest heat, the greatest depressions regions of the greatest cold; and if we fix our attention on these great regions only, they can be adequately rendered into bright and dark bands respectively, but the detail is comparatively ill rendered without a special adjustment, which would in turn give a false presentation of the great masses of light and shade."

This treatment, illustrated by figures in the book, consists of blacking out the whole of the under side of the curve and most of the upper side, but leaving as a transparent spot a small area at the vertex of each marked depression, the size and shape of the area depending on

[1] "Annals of the Astrophysical Observatory of the Smithsonian Institution." Vol. i. By S. P. Langley, Director.

the form of the curve. When this plate is photographed, a series of dark lines, the intensity of which depends on the size and shape of the corresponding transparent areas, is produced. By superposing this photograph on the former one which gave the general distribution of light and shadow, a representation of the linear spectrum of the bolograph is obtained. Clearly, considerable skill and judgment are required in such a process, and the linear spectra are only introduced to show the general effect and to enable the reader to compare the infra-red with the visible spectrum; the measurements of the position of the lines are all made on the selected bolographs themselves.

Chapter vii. contains an interesting account of the variations of absorption in the infra-red spectrum, which is shown to be the seat of great terrestrial atmospheric absorption, the relative intensities of energy changing greatly at different periods of the year in some portions of the spectrum, while in others they remain fairly constant in amount.

But little space is left to refer to Part ii., subsidiary researches, which to a student of theoretical optics may prove even more interesting than the main research. The first of these deals with the dispersion of rock salt and fluorite. It is sufficient, perhaps, to say that the dispersion curve for rock salt is drawn from wave-length $0{\cdot}5\ \mu$ to $6{\cdot}5\ \mu$, and the results compared with a formula —Ketteler's formula,

$$n^2 = a^2 + \frac{M_2}{\lambda^2 - \lambda_2^2} - \frac{M_1}{\lambda_1^2 - \lambda^2},$$

where

$$a^2 = 5{\cdot}174714$$
$$M_2 = 0{\cdot}0183744$$
$$\lambda_2^2 = 0{\cdot}015841$$
$$M_1 = 8949{\cdot}520$$
$$\lambda_1^2 = 3145{\cdot}695.$$

This formula agrees admirably over the whole range.

Another appendix gives a full account of the construction of the galvanometer used for the research. In this instrument, various sizes of wire were used in the different sections of the coil; its resistance was 28 ohms, and the external radii of the three sections of which each coil is composed are respectively ·383, ·741 and 1·632 cm.

Two magnet systems were tried, the one being 2·4 mgs. in weight, the other 6·5 mgs. With the former, which proved too light for the work, a deflection of one millimetre at a distance of one metre was given by a current of 5×10^{-12} ampere; with the latter the current required was 23×10^{-12} ampere.

Enough, perhaps, has been written to indicate the interest and importance of the work. Prof. Langley is to be congratulated in having brought it to so successful a conclusion.

R. T. G.

SOUTH AMERICA.[1]

IN the volume under notice, Mr. A. H. Keane gives a much needed compendium of the geography of South America. Since its independence from Spain and Portugal, that half-continent has been making great commercial strides, until its trade now equals in value that of British India. The importance of its varied products, its peculiar ethnological history, its wonderful physical features, its modern political advancement, make it a region of constantly increasing interest to the merchant, the man of science, the student and the statesman; while the fact that only about five-sevenths of it have thus far been explored and partially mapped makes it a favourite field for the geographer. Mr. Keane appears to have understood exactly what the world in general required from his able pen, and instead of confining himself to geography pure and simple, as the title of his work indicates, he has taken his subject in its most comprehensive sense. He gives us, in three preliminary chapters, the physical features of the country, its orography, great plains, plateaux, fluvial systems, seaboard, fjords, outlying islands, climate, flora and fauna and a valuable dissertation upon the ethical and later ethnical and historical relations of its much scattered tribes. He holds it to be "beyond reasonable doubt that man had spread in early Pleistocene times from his eastern cradle to the New World, probably by two routes —from Europe by the still persisting land connection with Greenland and Labrador, and, from Asia, by the narrow Bering Strait." He bases this assertion upon the fossil remains of man which are found in North and South America, "representing the two primordial types, which may be called the long-headed Afro-European and the round-headed Asiatic. These, strange to say, are found in far greater abundance in the southern than in the northern division." . . . "The inference seems inevitable that South America was already in Pleistocene times peopled to its utmost limits by two primitive races that still persist in the same region"—a statement which admits of doubt. "The long-heads are believed to have been the first arrivals . . . and later the round-heads," the latter "generally keeping to the Pacific side." The former are supposed to have afterwards migrated from their early settlements in southern Brazil and Argentina over a greater part of eastern South America.

There is no more delightful and vexatious field for anthropological and ethnological research than South America. The physical alterations which it has undergone, even in very recent geological periods, the separation of its eastern from its western portion by immense inland seas, the vast denudation of the orographic system of the Brazilian and the recent uplifting of the Andean section, the formation of its wonderful rivers, all probably largely effected since the occupation of the continent by man, have woven many factors into the problem of racial development there. The few traces which forgotten peoples have left under extraordinary physical changes and climatic influences, and the fragmentary knowledge existing regarding South American tribes, make it appear venturesome to indicate the routes by which their progenitors first penetrated the southern half of the New World. The problem seems to require more study than it has yet received before its solution can be safely approached. But the somewhat extensive remarks of Mr. Keane upon South American ethnology are very valuable—doubly so from the fact that he not only summarises his views in his "General Survey," but elaborates them as he afterwards passes each country in review, thus making his work of great importance to the student of tribal origin and development on the western continent. Mr. Keane justly comments on the purity of race in the United States in comparison with Latin America, "where all the ethnical elements have, from the first, tended to be merged in a fresh division of mankind, which may eventually acquire a uniform character, but must long continue to betray its diverse origins in the heterogeneous nature of its physical and mental qualities." And yet it is not entirely improbable that in several of the Spanish American States, notably Mexico and Bolivia, the mentally and physically strong native race are reasserting themselves, and absorbing, thinning-down and gradually dissipating the blood of their conquerors.

The description of each State includes its boundaries, so far as they are claimed or defined, its physical features, hydrography, climate, flora, fauna, inhabitants, wild tribes, topography, chief towns, period of discovery, conquest, settlement, colonial rule, religion, education, natural resources, mineral and agricultural productions and a

[1] "Stanford's Compendium of Geography and Travel (new issue) Central and South America." Vol. i. By A. H. Keane. Edited by Sir Clements Markham, K.C.B., F.R.S. Pp. xxii + 611. (London: E. Stanford.) Price 15s.

historical outline, thus giving us, *á grandes rasgos*, the *data* sought by any one who desires, in a limited space, to acquire a general knowledge of the country.

Regarding Venezuela, "it is still mainly inhabited by scattered rural communities and nomad tribes, with scarcely any large industrial or commercial centres." As to the Orinoco River system, "these magnificent inland waters are at present utilised in a regular way only by a single steamer, plying once a fortnight between Trinidad and Ciudad Bolivar," which is the only town of any importance on the Orinoco. To this river Mr. Keane gives a fall of about nine inches to the mile in a distance of 1300 miles, counting from the Cassiquiare Canal, that remarkable connecting link between the waters of the Orinoco and the Amazon. It is doubtful if the average slope is more than three inches to the mile, the mistake arising from the elevation of 920 feet above sea-level, which Mr. Keane assigns to the Cassiquiare, which probably does not exceed 335 feet elevation. This is one of the most important elevations in the interior of South America, and, since remote times, it has largely governed its hydrographic conditions. There is no part of the world where there is greater confusion in altitudes and distances, and the writer on the geographical features of South America often finds his patience sadly taxed by the disagreement between travellers and explorers regarding measurements.

The States of Colombia and Ecuador form interesting chapters of the work under consideration. The former, which is just terminating a most bloody and disastrous politico-religious war, aggravated by the influx of a swarm of Philippine friars, is a land where nature seems to have overlooked no favours within her power to bestow, and Mr. Keane pictures them with graphic pen. As to Ecuador, the most dormant of all the South American States, he says :—"The backward state of the agricultural interests is no doubt partly due to the constant political ferment which drives off capital, but also in great measure to the feudal system of land tenure. The whole country belongs to a few absentee owners, whose estates are often of boundless extent." He is right in part, but the religious institutions should have been included among the proprietors of the country *and its people*. It would also have been well to add that the interior of Ecuador, since the Spanish conquest, has had contact with the outer world by only two mule-tracks, both intransitable during the rainy season, and that, behind the coast cordillera, the priest has, for more than three centuries, had undisturbed opportunity to try his theories of progress. The result has been disastrous to the morals and advancement of the people, who are sunk in intellectual and physical degradation.

Peru, Bolivia, Chile, the Argentine Republic, Paraguay and Uruguay are treated according to their relative importance ; but sometimes the reader craves greater detail upon many interesting points, probably unwillingly withheld and retained in the abundant stores of information apparently in possession of the author.

In general, the maps which accompany the work are unworthy of the text ; old geographical errors are reproduced, and the maps are in no sense up to date, except those of Chile and the Argentine Republic, *which are more than up to date* ; for the question of limits between these countries, which is now under arbitration by the English Government, is apparently decided entirely in favour of Chile, although upon what grounds does not appear, as Mr. Keane and the editor, Sir Clements Markham, have wisely avoided any expression of opinion on the subject. One must therefore attribute to the publisher the glaring inconsistencies between *his* maps and the text of the work, it being evident that the author is not responsible for them. The boundary, as laid down between Chile and Argentina, is only of value in one sense—it shows the extent to which Chile hopes the English umpires will allow her to push her claims. The line could not have been better traced by the Chilian Foreign Office. To Chile alone it is useful ; but the public expect that a map publisher of

Lake Nahuel-huapi, in the Andes of north-western Patagonia.

repute will hold an even balance where boundaries are *sub judice.*

In the case of the Chile-Bolivia boundary, it appears that the publisher also considers that Bolivia has no territorial rights which Chile is bound to respect.

Mr. Keane closes his work with an extensive and valuable chapter on Brazil, a country which occupies nearly one-half of the area of South America. His remarks upon the "ethnical elements of the population and their distribution" he considers of value in estimating the probable political future of the Republic. "The triple fusion of aborigines, negroes and Europeans is mainly confined to the Atlantic States between the Amazon estuary and Rio de Janeiro. Then follow the States of San Paulo, Paraná, Santa Catharina and Rio Grande do Sul, with which must be grouped the vast and relatively populous region of Minas Geraes. Here we have no triple fusion, the negro element being everywhere mainly absent; but, as in Spanish America, an amalgam of aborigines and whites . . . which constitute the second section of the Brazilian people, distinguished from the first by the absence of black blood. Lastly, the aboriginal element tends to disappear in the direction of the south, where the white element is continually strengthened by direct accessions from various parts of Europe, but especially Italy, Portugal and Austria."

As to the above quotation, the State of Minas Geraes is the most populous in Brazil, and the negro element is everywhere in evidence; and instead of an "amalgam of aborigines and whites," few of the inhabitants are free from negro blood. Exclusive of the aboriginal tribes, one seldom finds any traces of Indian blood among the Brazilians except in the immediate vicinity of the banks of the main River Amazon.

Notwithstanding a few details where we might disagree with Mr. Keane, he has given us a most useful work of reference; but every reader at all familiar with South American geography will regret that the maps are not more trustworthy. GEORGE EARL CHURCH.

ZONES IN THE CHALK.

ATTENTION was directed in NATURE for April 26, 1900, to Dr. A. W. Rowe's researches on the zones of the White Chalk of Kent and Sussex. Dr. Rowe has since published his observations on the White Chalk of Dorset (*Proc. Geol. Assoc.*, vol. xvii. part i. 1901). Aided in the field as before by Mr. C. Davies Sherborn, the author has made a particular study of the higher portions of the Chalk which commence with the zone of *Rhynchonella Cuvieri.*

Those who are familiar with this portion of the Dorset coast, or have read Mr. Aubrey Strahan's explanatory memoir (published by the Geological Survey), know how faulted and crushed are the strata in many places, and how difficult or impossible of access are many portions of the cliffs. Undaunted, however, by these obstacles, or by the hardness of the Chalk and the trouble in extracting and preserving the often shattered fossils, Dr. Rowe and Mr. Sherborn "have been able to fix, with varying degrees of accuracy, the limits of nearly every zone," and to record from each a characteristic fauna. While confirming the general conclusions of Dr. Barrois, they have amplified our knowledge to a remarkable extent, and have had the satisfaction of determining the presence, hitherto unsuspected in the region between White Nothe and Studland Bay, of the higher Chalk zones of *Actinocamax quadratus* and *Belemnitella mucronata.*

That zones in the Chalk are purely zoological divisions is thoroughly borne out in this paper, and although it is remarked that "nothing but rigid collecting gives one the faintest chance of obtaining the junction between the various beds," it is evident that no more definite boundary is to be expected between zones than that which in human chronology separates one century from another. Here and there particular flint-bands, the nodular character or the colouring of the Chalk afford local guides for marking approximate junctions or for tracing horizons from place to place amid the complex disturbances of the strata; and these have been carefully noted. Dr. Rowe, indeed, felt some "anxiety to find a lithological feature" whereby to permanently mark the planes of division he took, but this was seldom possible, nor could it reasonably be expected in such a comparatively uniform series of strata. Nevertheless, the results of Dr. Rowe's painstaking work have been in many instances permanently recorded in a series of beautifully executed plates prepared from photographs taken by Prof. H. E. Armstrong. Diagrams accompany these plates to show the positions of the several zones and the limits assigned to them. No higher testimony to the value of zones has, perhaps, ever been given in this country, for the authors have had a veritable geological puzzle to deal with, and they have interpreted it by means of their long experience of Chalk fossils and by assiduous collecting. By these means the knowledge elsewhere gained where the sequence is unbroken has been applied with marked success, and the progressive changes in the life-history of the Chalk have been found to correspond with a precision that could not have been expected in strata deposited under more varying conditions. While the zones are marked out within narrow limits by certain dominant species, yet where these zonal forms are absent the "zones are often as accurately defined by their associated guide-fossils." These are noted with reference to Dorset.

It may be observed that, with the exception of *Marsupites*, *Actinocamax quadratus* and *Belemnitella mucronata*, the dominant forms are not confined to the zones they characterise. The author makes some remarks on the varying position of the layers described as Chalk Rock. No doubt any type of rock may be found at any horizon, but it must be remembered that the limits assigned to Chalk zones are approximate. There is nowhere any real boundary, and even some dominant types may have existed in abundance longer in some areas than in others. H. B. W.

THE ORIGIN AND HABITS OF THE BACTRIAN CAMEL.

OF few of our larger domesticated animals is the origin so buried in mystery as is that of the camels. Till a few years ago, indeed, naturalists were in doubt whether the two-humped Bactrian species was really a native of the countries where it is now kept in a domesticated condition. The probability was, however, all in favour of such being the case; and the recent discovery of remains of fossil camels in several parts of Europe, as well as the occurrence of such remains in Asia, afford strong corroborative evidence that eastern Europe and northern Asia formed the original habitat of the wild Bactrian species.

The subject has recently been discussed in *Globus* for May 2, 1901, by Dr. A. Nehring, of Berlin, who expresses himself in favour of the view that some, at least, of the two-humped camels which roam at liberty over the wastes of the Gobi are indigenously wild animals.

Years ago the occurrence of remains of fossil camels (*Camelus sivalensis*) was recorded by Falconer and Cautley in the Tertiary strata of the Siwalik Hills of northern India. The dentition of this species is numerically the same as in the two living members of the group; and from this circumstance, coupled with the well-known affinity between the extinct fauna of the Siwaliks and that of Africa at the present day, it is not improbable that the Siwalik camel was the ancestor of the single-humped African species, since, as will be shown below, there is a probability that the ancestor of the Bactrian species had a fuller dental series.

And here it may be well to mention that in adult modern camels there are normally five pairs of cheek-teeth in the lower jaw behind the tusks, or canines. The first pair (the first premolars) are, indeed, somewhat like a canine in form, and are separated by a gap from the canine in front and from the remaining four of the cheek-teeth behind. Of the latter, the last three pairs are the true molars, while the tooth in front of them represents the last of the typical series of four premolars.

Now in the lower jaw of a fossil camel recently described from the Pleistocene Tertiary strata of Rumania, by Herr Stefanescu, under the name of *Camelus alutensis*, there are six, in place of five, pairs of lower cheek-teeth, the tooth representing the third lower premolar being developed. Evidently we have here an ancestral type of camel, and it is noteworthy that, according to Dr. Nehring, this supernumerary lower tooth occasionally makes its appearance in living camels, although it is not mentioned in which species. The remains of the Rumanian camel were discovered on the left bank of the Aluta (Olt) river, a tributary of the Danube, not far from Slatina.

Evidently, remarks Dr. Nehring, this Rumanian camel was a member of the steppe-fauna, of whose former existence in central Europe evidence is afforded by the occurrence of fossil remains of the saiga, Kirghiz jerboa and other species now characteristic of the Volga steppes. Another fossil camel has also been described, under the name of *Camelus knoblochi* or *C. volgensis*, from strata in the neighbourhood of Sarepta, on the Volga, and also at the mouth of the Tscheremschan, in the Government of Samara, the number of lower teeth in this species being apparently the same as in modern camels.

As members of the steppe fauna, these Rumanian and Russian fossil camels were almost certainly the ancestors of the living Siberian species; and since the Rumanian species has a larger number of lower teeth than the still older Siwalik camel, it is manifest that the latter cannot have been the progenitor of the Bactrian species. Hence the reason for regarding it as the ancestor of the single-humped camel of Africa. The Russian camel-remains, it may be added, were found in association with molars of the mammoth.

Remains of camels have also been found in the Pleistocene strata of Oran and Ouen Seguen, in Algeria; and certain remains from the Isle of Samos have recently been assigned to the same genus, although the reference requires confirmation. The Algerian Pleistocene camel was doubtless the direct ancestor of the living African species, which it serves to connect with the extinct *C. sivalensis*.

With regard to the camels of the Gobi, which, as already mentioned, Dr. Nehring regards as truly wild, it is interesting to note that some years ago Dr. Langkavel described them as being much smaller than the domesticated breed, not, indeed, much superior in size to a horse with relatively slender limbs. Observations in confirmation of this statement are, however, urgently required; and any travellers who may visit the Gobi neighbourhood would do service to science if they would bring back skins and skeletons of the wild camels.

Nothing is more remarkable in connection with the Bactrian camel than its capacity for standing extremes of heat and cold, provided always that the climate be dry. Herr O. Lehmann (*Zeitschr. wiss. Geographie*, 1891, p. 27), for example, writes as follows:—

"The most severe winter cold of Asia cannot prevent the presence of the camel. In west Siberia, from the Kirghiz steppe to the neighbourhood of Lake Baikal, are camels found. . . . In Semipalatinsk the mean winter temperature falls to $-21^{\circ}\cdot9$ C.; the most intense registered between the years 1854 and 1860 was $-49^{\circ}\cdot9$. During his journey Przewalski experienced the most intense cold without losing a single camel. Throughout his whole journey across the Mongolian plateau he daily encountered a temperature of -37°. . . . Again, in Zaidam, where camel-breeding establishments exist, a night temperature of $-23^{\circ}\cdot6$ was observed, which in November was intensified to $-25^{\circ}\cdot2$. In the neighbourhood of Tarai-nor, on the 50th parallel of north latitude, the Burjæts keep numerous camels, which even in winter are allowed to wander about without the slightest protection. . . . Here the camel reaches the 50th parallel, westward of Lake Baikal, on the Upper Yenisei, where the Samoyeds keep both reindeer and camels. Here, indeed, the breeding-area of the camel overlaps that of the reindeer."

In regard to its capacity for heat, the same author records the following observations:—"If the degree of cold that the Bactrian camel can withstand is wonderful, not less remarkable is the heat it can undergo. In the Gobi Desert Przewalski took the temperature of the ground in summer and found it to be $62^{\circ}\cdot5$ C." R. L.

NOTES.

We regret to see the announcement of the death of Prof. W. Schur, professor of astronomy in the University of Göttingen.

The Antarctic exploration ship *Discovery* was inspected by the King and Queen at Cowes on Monday. Their Majesties were received by Sir Clements Markham, K.C.B., who presented Commander Scott, who in turn presented the officers of the ship and the scientific staff. The King showed great interest in the laboratories and the instruments for scientific work, which were explained by Mr. George Murray, F.R.S., who accompanies the ship to Melbourne, and Dr. H. R. Mill, who will go as far as Madeira in order to start the oceanographical observations on the way out. The ship left Cowes on Tuesday, with hearty wishes for a voyage free from calamity and fruitful in scientific results.

We understand from the *Irish Naturalist* that Prof. A. C. Haddon, F.R.S., intends to resign the chair of zoology at the Royal College of Science, Ireland, which he has occupied since 1880, in order to devote more time to anthropological work.

The death is announced, at San Francisco, of Dr. H. W. Harkness, known for his contributions to entomology and botany. For several years Dr. Harkness was president of the California Academy of Sciences, to which institution he presented his large collections of specimens of cryptogams.

The *Express* states that Profs. Haeckel, Conrad and Fraas, of Jena, Halle and Stuttgart Universities respectively, announce that the sum of 1500*l*. has been placed at their disposal as a prize for the best work on the question, "What do we learn from the principles of the theory of heredity in reference to the inner political development and legislation of States?" Manuscripts must be in German and sent not later than December 1, 1902, to Prof. E. Haeckel, Jena.

According to a *Times* correspondent, Dr. Berson and Dr. Suering, who made a balloon ascent from Berlin on July 31 and descended near Kottbus in the morning of the following day, succeeded in reaching an altitude of more than 10,300 metres. It was impossible to ascertain the greatest altitude attained, as both the aëronauts lost consciousness in consequence of the rarity of the air. The minimum temperature registered was -40° C.

We learn from *Science* that, aided by a special fund presented by a friend of the American Museum, Prof. Osborn recently sent out two expeditions especially in search of fossil horses—

one to Texas and one to eastern Colorado. Word has just been received at the Museum that the very first discovery made by the Texas party included a deposit of skulls of the three-toed horse, Protohippus, associated with parts of the limbs, feet and backbone. This is one of the stages especially desired in the long series leading up to the modern horse. The skulls are reported to be the best that have thus far been found, and this discovery is an auspicious opening to this special series of explorations.

THE fifth annual Fungus Foray of the British Mycological Society will be held at Exeter from Monday to Saturday, September 23–28. The club dinner will be held on September 24, after which the president, Prof. H. Marshall Ward, F.R.S., will deliver his presidential address. On September 25, Miss A. Lorrain Smith will read a paper on "The Fungi of Germinating Farm Seeds," and on the following day a paper on "Spore Formation in Yeasts" will be read by Mr. Barker.

IT has been found that one of the most effective methods for destroying locusts in humid climates is by propagating among them the well-known fungus disease. The Cape of Good Hope fungus, described by Dr. Sinclair Black, is the *Empusa acridii*. To employ it, a culture is prepared on moist bread crumbs and scattered in places frequented by the locusts. The locusts which consume the bread die, and their bodies are eaten by other locusts and thus the disease spreads. The method is less effective in dry weather.

MR. C. A. BENBOW, writing in the *Agricultural Gazette of New South Wales*, strongly recommends the introduction of the eland of Cape Colony into the scrub lands of New South Wales and Central Australia. This scrub land is almost valueless as pasture, especially in years of drought. The eland is, however, accustomed to feed on the same leguminous shrubs in South Africa which form the scrub of Australian lands. The animal is one of the largest of the antelopes, often equalling an ox in weight, is easily domesticated and produces meat of exceptionally fine quality.

IN the *Bulletin* of the American Geographical Society (No. 3, 1901), Mr. R. de C. Ward gives a note on the climate of Mammoth Tank, situated in the southern portion of the Colorado Desert, and one of the most interesting places in the United States from a meteorological point of view. The mean temperature of July is 98°·5, and of January 53°·9. The highest temperature recorded was 130°, in August, 1878, and the lowest 22°, in December, 1895, giving an absolute range of 108°; temperatures of 100° and over have been recorded in every month of the year except the four winter months, November to February. The mean annual rainfall for twenty-three years is 1·81 inches; the greatest amount in any one year was 5·48 inches, while in the two years 1897 and 1898 there was only a trace.

AN interesting paper was recently submitted to the Royal Academy of Belgium, by Dr. E. Vanderlinden, on the atmospheric conditions that accompany fog in that country. The inquiry is based upon an examination of some 200 synoptic charts, the winter and autumn fogs being studied separately from those which occur in summer. The author shows that the winter fogs are mostly connected with anticyclonic conditions, while those of summer occur during periods of shallow or secondary barometric depressions. The winter fogs rarely occur on the western side of an area of high barometric pressure. In reporting to the Academy upon the paper, M. Lancaster points out that most authors who treat of the question of the formation of fog only deal with very local areas, in which temperature plays the principal part, but that this kind of fog should not be confounded with the general phenomenon characteristic of winter fogs, which depend upon the barometric pressure. The most favourable conditions for fog formation are damp air and a temperature a little above freezing point. These conditions generally occur in winter with westerly winds and when the centre of the high-pressure area lies to the south-east of the point of observation, but M. Lancaster points out that the action of temperature alone is not sufficient to explain completely the occurrence of certain types of fog.

SINCE the article upon the recent work of the United States Weather Bureau appeared in NATURE of May 23 (p. 80), the Report of the Chief of the Bureau on the operations during the year ending June 30, 1900, has been received. In addition to the usual tables containing the results of observations made at Weather Bureau stations in the United States, Mr. E. B. Baldwin gives a detailed account of the meteorological observations made by him in Franz-Josef Land during the second Wellman expedition in 1898–1899. The lowest temperature experienced seems to have been recorded on February 1, 1899, when a minimum of forty-five degrees below zero Fahrenheit was observed. The means of the maximum and minimum temperatures recorded by the thermograph in the first three months of the year 1899 are as follows, in degrees Fahrenheit:—January, max. −10°·9, min. −24°·0; February, max. −5°·4, min. −19°·4; March, max. 16°·7, min. −26°·8. A very complete record of auroral phenomena was kept by Mr. Baldwin, and has been published in the U.S. *Monthly Weather Review* for March, 1901.

THE representation of electromagnetic phenomena by mechanical models was brought into prominence many years ago by Maxwell's well-known model of a dicyclic system representing the mutual induction of two currents. Prof. Garbasso now sends us a number of papers dealing with the construction of mechanical models representing the discharge of condensers, in particular in the case when the armatures of a condenser are connected by two wires in parallel. The most recent of his papers, dealing with the maximum value of the electrokinetic energy of mutual induction of two currents and its physical interpretation, appears in the *Nuovo Cimento* for June (5, i.)

A NOTE on some discontinuous and indeterminate functions by Mr. Charles Kasson Wead in the *Bulletin* of the Philosophical Society of Washington is rather suggestive. The treatment is based on the fact that if $u = (x/a)^\infty$, $u = 0$ or ∞, according as $x <$ or $> a$, so that if N is any positive number greater than unity, $N^{-u} = 0$ or 1 according as $x >$ or $< a$. By means of this factor the author shows how it is possible to construct equations representing broken lines or portions of plane areas within or without given plane curves. As physical applications, the author shows how to represent by a single expression the potential of a solid sphere, or the attraction of a spherical shell at points both inside and outside the sphere.

WE have received several papers by Prof. Sommerfeld, dealing with the theory of the diffraction of Röntgen rays. One of these is published in the *Zeitschrift für Mathematik und Physik*, xlvi. 1, 2, and abstracts are also given in the *Physikalische Zeitschrift*, ii. The special problem which forms the subject of Prof. Sommerfeld's work is the mathematical investigation of the results of the hypothesis put forward by Wiechert and Stokes, according to which Röntgen rays consist in an impulsive disturbance propagated through the ether. The author considers the problem of diffraction past a screen in the form of a half-plane and allied problems, and compares his results with those found by Haga and Wind and others. The single non-periodic impulse may be said to represent one extreme case of ray-propagation, while the purely periodic wave represents the other extreme. While actual Röntgen rays and light-rays probably only approximate to these extreme cases, the agreement between Prof. Sommerfeld's conclusions and experimental results affords considerable evidence in favour of the above theory of Röntgen rays.

IN the *Johns Hopkins University Circular*, No. 152 (vo . xx. pp. 79–80), Mr. C. C. Schenck gives a short description of a series of investigations undertaken with the twofold object of (1) separating the principal lines in the spark spectrum of cadmium into three groups having characteristic properties, (2) studying the constitution of the various regions of the spark and its spectrum by means of a revolving mirror. It was found that a preliminary division of the spectrum lines into groups was feasible by noting the changes produced in the spark spectrum when the period of the condenser in the secondary circuit was varied by increasing the self-induction. Kirchhoff in 1861, and Thalen in 1866, stated the effect in general terms, and Hemsalech has recently carried the investigation much further. The spark was produced by an induction coil supplied with alternating current; secondary condenser about ·016 microfarad, spark length 6–8 mm. The spectrum was photographed with a large concave grating of 21 feet radius. The three groups of lines described appear to correspond to the well-known "long" and "short" lines always seen when an image of a light source is thrown on the spectroscope slit, but no wave-lengths are given for comparison. It is stated, however, from an examination of the conditions giving rise to the three groups of lines, that the average temperature of the metallic vapours in the arc is probably *higher* in some cases than in the spark. The experiments with the rotating mirror indicated that the chief arc lines had a duration more than twice as great as that of the chief spark lines. Also that the principal spark lines (both of cadmium and magnesium) are due almost entirely to the curved streamers seen branching from the spark, while the chief arc lines are due in part to the streamers and in part to a luminosity which fills up the spark gap and persists after the streamers cease.

THE "Birds of Western New York" is the title of an article by Mr. E. H. Eaton which appears in vol. iv. of the *Proceedings* of the Rochester (N.Y.) Academy of Science. Although at first sight this may appear nothing more than an ordinary local fauna-list, it is really worth the best attention of every naturalist on account of the elaborate manner in which the subject is treated. Specially noteworthy are the diagrammatic "migration and residence tables," in which it is attempted to show graphically "the times of occurrence and relative abundance of the birds definitely recorded for this region." The essay is, in fact, an admirable example of the way in which local faunas should be recorded and described.

THE most noticeable feature in the Report of the American Museum of Natural History for 1900 is the number of expeditions which have been undertaken with the view of adding to the ethnological and palæontological collections. Although the majority of these were confined to North America, one—the Jesup North Pacific Expedition—was despatched to the Amur valley, while two were sent to South America. The former, it is reported, has brought back a valuable series of specimens illustrating the ethnology and anthropology of the Ainu of Japan; while of the two latter, the mission to Patagonia has acquired a valuable collection of the extinct mammalian fauna of that country. But the amount of strictly scientific work accomplished has not hindered attention being paid to the educational function of the Museum; and the president, in his report, calls special attention to the opening of the new and spacious "auditorium," where secondary education is to be offered to the public in the form of popular lectures.

DR. B. HAGEN gives in *Globus* (Bd. lxxix. p. 245) a beautifully illustrated account of his ascent of Kaba, in Sumatra, which is 1650 metres in height. This volcano has previously been ascended by A. W. P. Verkerk, R. D. M. Verbeek and H. O. Forbes.

THE Berlin Museum für Völkerkunde has recently been enriched by the addition of a number of wooden human effigies from German New Guinea, some of which are described and figured in *Globus* (Bd. lxxix. No. 22, p. 352) by D. Rudolf Pöch. The head appears to be hidden in most of them by a mask, which has a long beak which looks more like a snout than a bird's beak; but from the carving above its insertion there can be little doubt that the bird that is represented is the hornbill, which is a magical or symbolic bird all over the Malay region and throughout the greater part of New Guinea as well. On the top of the mask a figurine of a cuscus is often carved. We still await an explanation of these remarkable objects.

THERE is an interesting little paper by M. Félix Regnault, illustrated by numerous figures, in the *Bulletin de la Société d'Anthropologie de Paris*, 1900, No. 6, on Greek terra-cottas from Smyrna. In the hundreds of specimens in the Museum in the Louvre there are many beautiful ones after the manner of the famous figurines from Tanagra and Myrina; some are grotesque, others are ethnic types, anatomical studies and even illustrations of pathological conditions. It is with the latter that the present paper deals. Various examples of facial deformations are given, such as facial paralysis and adenoid growths. Pronounced acrocephaly and scaphocephaly, as well as illustrations of idiots and degenerates, were moulded by these observant potters. The other articles in this journal are mainly of interest to professional anthropologists.

IN his "Laboratory Outlines for use in an Introductory Course in Somatology" (*American Anthropologist*, n.s. vol. iii. p. 28), Mr. Frank Russell has hit on a very useful idea, which, however, is susceptible of improvement. For example, no indication is given of the system of head-form nomenclature introduced by Sergi; the system of the Italian anthropologist, as a whole, may be cumbersome and difficult to grasp, but his primary forms are readily recognisable and are of distinct classificatory value. Like the majority of anthropologists, Mr. Russell omits the valuable series of radial measurements that are taken from the ext. aud. meatus and which can be compared with similar measurements made on the living. The prosopic, &c., measurements should be placed in the nasal and not in the orbital category. If Mr. Russell were to reconsider his schedule in some details and were to state where the terms, measurements and indices were described in readily accessible publications, or, better still, were to republish this information, he would produce a pamphlet which would be of very great use to students of physical anthropology.

MR. JAMES STIRLING, Government geologist of Victoria, has prepared a report on the brown coal industry in Germany and Austria, which has been issued by the Department of Mines, Victoria, through the Agent-General in London (1901). The main object is to promote a similar development of brown coal production in Victoria, where such fuel would be of service on branch railway lines and for goods traffic where a slow rate of speed is maintained.

FROM Indiana we have received the twenty-fifth annual report for the Department of Geology and Natural Resources of the State geologist, Mr. W. S. Blatchley. A large part of this report is taken up with particulars about marls and limestones and the manufacture of cement; the petroleum industry is also dealt with, and Mr. Blatchley describes two new species of salamanders from Tennessee. In addition, there is a monograph on the Devonian fossils and stratigraphy of Indiana, by Mr. Edward M. Kindle. The fossils are illustrated in thirty-one plates, and some new species of Mollusca and Brachiopoda are described.

THE Eocene deposits of Maryland are elaborately described and illustrated by Prof. W. B. Clark and Mr. G. C. Martin in one of the handsome volumes issued by the Maryland Geological

Survey (1901). Materials do not exist for a detailed correlation of the strata with those in Europe, as the few identical species have a wide range in time, but there is little doubt that the Maryland deposits represent a considerable portion of the Eocene series. In the palæontological section the authors personally deal with the Echinodermata, Brachiopoda and Mollusca, and have been aided by specialists in other groups. The work is illustrated by pictorial views, maps and sections, and numerous figures of fossils.

WE have received the general report of the Director, Mr. C. L. Griesbach, on the work of the Geological Survey of India for the year ending March 31, 1901. Eight officers have been occupied in field-work. Among the regions examined are the Shan States in Burma, where great difficulties had to be encountered in the extensive forests and dense undergrowths, while frequently the actual rock is covered by a soil-cap fifty or more feet in thickness. Evidence has, however, been obtained of older crystalline rocks and of Lower Silurian or Ordovician, while the occurrence of Devonian, which had been inferred by Mr. P. N. Datta, has been confirmed by Mr. La Touche, who found *Calceola sandalina*. The presence of Triassic rocks was first recognised by Mr. Datta. In Assam, Tertiary, Cretaceous and older strata have been mapped by Mr. P. N. Bose; in Himalayan regions, Dr. A. von Krafft has been at work on Triassic rocks; and in Baluchistan Mr. E. Vredenburg has examined the complicated structure of the Chapar range, where numerous folds and overthrusts occur among Cretaceous and Tertiary strata. The subject of landslips has been locally dealt with by Mr. T. H. Holland, and special attention has been given to gold-bearing regions and to water-supply. In palæontology, aid has been received from Dr. F. L. Kitchin in England, Prof. Dr. Uhlig in Austria and Prof. R. Zeiller in France.

ONE of the recent publications of the Geological Survey of Egypt is devoted to a description of Farafra Oasis, by Mr. Hugh J. L. Beadnell. This wide depression, the "Land of Cattle" of the ancient Egyptians, lies in the Libyan Desert far west of Assiut, one of the most important towns of Upper Egypt. Although occupying a large area, the oasis appears to be of little importance from an economic point of view, being, in fact, a stretch of low desert with about twenty isolated "bubbling springs" (Farafra), most of them on the western side. The water is entirely derived from white, chalky limestone of Upper Cretaceous age, which, as observed by Prof. Zittel, forms the plain and is overlaid by Lower Eocene beds, the strata being bent into a gentle anticline. The depression has an irregular triangular shape with the apex to the north and is bounded by steep cliffs of Eocene strata on the east and west, while to the south the floor rises gradually for many miles until a distant escarpment is reached. A large part of the floor is covered with blown sand, and the action of this drifting material has eroded the chalk and left on the surface of the plain numerous fragments and masses of iron pyrites and marcasite derived from that formation. The author differs from Zittel in believing that there is a considerable break between the Cretaceous and Eocene strata. The former rocks are grouped as belonging to the Danian division, but the fossils have yet to be critically examined.

THE additions to the Zoological Society's Gardens during the past week include two Indian Wolves (*Canis pallipes*) from India, presented respectively by Colonel Lloyd and Mr. W. B. Cotton; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Miss E. M. Berney; a Demoiselle Crane (*Anthropoides virgo*), a Lesser Black-backed Gull (*Larus fuscus*) from North Africa, presented by Dixon Bey; a Puffin (*Fratercula arctica*), British, presented by Mr. H. C. Price; a Cinereous Vulture (*Vultur monachus*), three Indian Rat Snakes (*Zamenis mucosa*) from India, presented by H.E. Sir H. A. Blake, G.C.M.G.; two American Jabirus (*Mycteria americana*) from South America, presented by H.E. Sir W. J. Sendall, G.C.M.G.; three Chameleons (*Chamaeleon vulgaris*) from North Africa, presented by Mr. A. Robinson; a Patas Monkey (*Cercopithecus patas*), a Green Monkey (*Cercopithecus callitrichus*), a Campbell's Monkey (*Cercopithecus campbelli*), a Bell's Cinixys (*Cinixys belliana*), an Eroded Cinixys (*Cinixys erosa*) from West Africa, a Pinche Monkey (*Midas oedipus*) from Colombia, two Springboks (*Gazella euchore*) from South Africa, two Small Hill Mynahs (*Gracula religiosa*) from India, deposited; two Common Jackals (*Canis aureus*), two White Cranes (*Anthropoides leucogeranos*), two Imperial Fruit Pigeons (*Carpophaga*, sp. inc.), a Purple-shouldered Pigeon (*Crocopus phoenicopterus*), three Andaman Teal (*Querquedula albigularis*) from India, received in exchange.

OUR ASTRONOMICAL COLUMN.

SEARCH EPHEMERIS FOR ENCKE'S COMET.—A circular from the Centralstelle at Kiel furnishes the following ephemeris for the expected appearance of Encke's Comet:—

Ephemeris for 0h. Berlin Mean Time.

15	7 6 56	...	+30 22·2

VARIATION OF EROS.—In the *Comptes rendus*, vol. cxxxiii, pp. 262–265, M. André presents the results of the reductions of observations made at the observatory of Lyons since February 1901. Three observers made independent estimations of the magnitude of the planet at intervals of five minutes. It is notable that the determination of the times of minima appears much more accurate than that of the maxima, the mean errors from a single observation in the two cases being ± 3·3 and ± 7·2 minutes respectively.

From the whole of the observations the period deduced is

5h. 16m. 15·2s.

Further notes are given concerning the change in form of the light curve, consisting chiefly in the two sections becoming more nearly equal than was the case when the variability was first detected.

CELESTIAL OBJECTS HAVING PECULIAR SPECTRA.—*Circular No.* 60 from the Harvard College Observatory contains a list of 59 objects found by Mrs. Fleming from an examination of the Draper Memorial photographs, which exhibit peculiarities in their spectra. The positions are given for 1900, and accompanying notes describe the special features of the objects, which include 19 gaseous nebulæ, 6 bright line stars of Type I., and 22 stars of Type V. One of the gaseous nebulæ is noted as showing bright lines at λ5007, Hβ, Hγ, Hδ and Hϵ. A great number of these objects (28) are situated in the region of the Large Magellanic cloud.

It is also noted that the bright Hβ in the spectra of η Centauri (A.G.C. 17739), and κ Apodis (A.G.C. 20878), has been found to show indications of variability.

MOTION OF α PERSEI IN THE LINE OF SIGHT.—Prof. H. C. Vogel has responded to the appeal made by Mr. Newall for observations of the radial velocity of this star, which, from spectrograms obtained at the Cambridge Observatory, showed indications of a period of variability of 4·2 or 16·8 days. The spectra obtained at Potsdam are only about half the scale of the Cambridge plates. Photographs of the spectrum were obtained on six nights during November 1900, for preliminary testing, and others during December 1900 and January 1901, which were measured and reduced for velocity. The result of determinations from thirteen plates is given as −3·22 km., relative to the sun. No indication of variation is found, and the adopted velocity is in fair accordance with the value −2·4 km. obtained by Campbell. (*Astrophysical Journal*, xiii. pp. 320–323.)

METALS AS FUEL.[1]

A CAREFUL metallurgist,[2] writing in the eighteenth century, claimed that "every matter which is combustible either wholly or in part, is called fuel, the pabulum of fire." The word is, however, usually restricted to substances which may be burnt by means of atmospheric air with sufficient rapidity to evolve heat capable of being applied to economic purposes. The latter definition covers certain metals, though it was doubtless framed to include only carbon and associations of carbon and hydrogen, such as coal. The omission from the definition of the reference to atmospheric air would enable the list of metals which might be used as fuel to be widely extended.

It has long been known that metals will burn, and it would be easy to show that the history of inorganic chemistry is epitomised and enshrined in a mass of litharge, which is simply burnt lead. Successive generations of chemists, from Geber in the eighth century to Lavoisier in the eighteenth, studied litharge carefully before the latter proved partly by its aid the identity of respiration, calcination and combustion. Into this history I need not enter, but it may be pointed out that Sir Isaac Newton[3] had a clear idea as to the possibility of burning metals. "Is not fire," he asks, "a body heated so hot as to emit light copiously?" . . . "for what else is red hot iron than fire?" and he significantly adds, "metals in fusion do not flame for want of copious fume." He was, moreover, aware that a mixture of lead and tin "suitably heated" does emit "fume and flame," and, in fact, a mass of 1 part tin and 4 parts lead, which looks metallic, will, if it is kindled, continue to burn like an inferior variety of peat, leaving an ash-like product which may be used as an enamel.

I propose to show that metals may be burnt for the sake of the heat and light they produce, just as ordinary fuels are burnt, except that in burning ordinary fuels combustion is often effected in two distinct steps or stages, in the first of which carbonic oxide is formed, and in the second carbonic acid, the products in both cases being gaseous. When metals are burnt, the products of combustion are solid, or condense to solids, and they therefore present a marked contrast to ordinary fuels which, as has just been stated, yield on combustion gaseous products. As I shall have but little to say about the light which attends the combustion of metals, I may as well dismiss the subject by reference to a familiar application of the burning of metals for the purpose of illumination. It is easy to fire electrically a portion of what is known as a "magnesium star," and a "fire-ball" of magnesium attached to a parachute is beautifully packed in this shell, for the loan of which I am indebted to the authorities of the Royal Arsenal, Woolwich, and when the shell explodes the stars burn and illuminate the enemy's position in the darkness of night, so that guns may be laid to place projectiles in the enemy's lines.

Before proceeding further, I want to use the electric furnace as affording a basis of comparison with the method of producing high temperatures by the combustion of metals, which I shall proceed to show subsequently. A current of 100 amperes at 200 volts is passed by carbon poles into the furnace in which pig iron is being melted; directly the last piece of iron has become fluid, the temperature of the fused pool must be about 1300° C. The fluid mass is reflected on the screen merely to give some indication as to the appearance of such a mass at 1300° C., and not to afford a test of the capabilities of the electric furnace. Later on I hope to show that a far higher temperature can be produced by very simple means in a receptacle of about the same capacity as the laboratory part of the furnace.

Henceforth in the course of this lecture metals will be burnt for the sake of the heat which is the result of their combustion. From this point of view metallurgists have long used metals as fuel, often without due recognition of the fact, but case after case could be cited in which conducting definite metallurgical operations is made possible by burning portions of the metal or metals under treatment. Time will perhaps be saved if I place in sharp contrast the use of ordinary fuel and metallic fuel, even though it takes us rather far back, for I do not want it to be thought that the use of metals as fuel is new, although their adoption for this purpose has recently been greatly stimulated. Here is a mass of very ordinary iron ore picked up on a heath in Surrey, which skirts the site of what was once the ancient forest of Anderida. The pre-historic dweller on the heath who used the beautiful flint arrowheads, which are found near the iron ore, merely burnt the wood of the forest to warm himself or to cook his food. But the Britons whom Cæsar found in Andreaswold smelted iron with the wood of the forest trees, from which they prepared charcoal, and smelting iron was actively conducted in Queen Elizabeth's reign, and even survived into the last century in the district I am contemplating. But in smelting iron, carbon became associated with it and played a subtle part, rendering the iron precious for certain purposes and useless for others. Iron had therefore to be "decarburised" with a view to its conversion into steel, and in doing this metallurgists for centuries truly burnt some of the iron itself, using it actually as fuel. I will only add that the use of metals as fuel assumed magnificent proportions in the hands of Bessemer, as may be illustrated by an experiment. A few pounds of a compound of iron, carbon, silicon and manganese is melted in the wind furnace, simply used because it affords a convenient method of melting the mass, which is turned into a small Bessemer converter. A stream of oxygen is directed into the fluid mass. Air would do, but with so small a mass the free nitrogen would cool it too rapidly. In a few seconds the carbon in the fluid will be burnt away, nevertheless the mass gradually becomes hotter and hotter, notwithstanding the loss of carbon. A brilliant pyrotechnic display is the result. The metalloid silicon is now burning, and then brown fumes of iron and manganese pass freely off; these metals are truly burning and are maintaining the heat of the bath, and the presence of their fumes shows that it is time to stop the operation. The temperature is somewhere near 2000° C., but according to some recent investigations of Prof. Noel Hartley (*Phil. Trans.*, vol. cxcvi. series A, p. 479, 1901), a temperature of more than 2000° C. is attained in the converter. Bessemer gave the world in 1856 cheap steel; we therefore owe to him the inestimable benefits that are the results of that gift, and I ask you to bear in mind that his great service to the industry of which we as a nation are so justly proud rested on the possibility of using metalloids and metals as fuel. I have already promised that in the course of the lecture I will show some experiments in which the temperature will be a thousand degrees higher than in the one you have just seen. In the Bessemer process the products of combustion are both gaseous and solid, and in a very ordinary case the heat engendered by the carbon of the bath which evolves gases is only half that which results from the combustion of the silicon, iron and manganese which yield solid products. As regards the "open-hearth process," in the phase of it which is known as the "pig and ore" process, oxygen is presented and heat is produced under similar conditions to those we shall consider subsequently in the case of the action of aluminium on ferric oxide.

Heat Evolved by Burning One Gramme of the Following Elements.

Element.	Product of combustion.	Calories.
Aluminium	Al_2O_3	7250
Magnesium	MgO	6000
Nickel	NiO	2200
Manganese	MnO_2	2110
Iron	Fe_2O_3	1790
,,	Fe_3O_4	1580
,,	FeO	1190
Cobalt	CoO	1090
Copper	CuO	600
Lead	PbO	240
Barium	BaO	90
Chromium	Cr_2O_3	60
Silver	Ag_2O	30
Carbon	CO_2	8080
,,	CO	2417
Silicon	SiO_2	7830

This table, which contains the relative calorific powers of different metals and metalloids as compared with carbon, indicates the advantage which certain metals possess over carbon for use as fuel. The question at once presents itself, at what temperature will such metals as can be used for fuel begin to abstract oxygen from the air? The answer is, it depends on

[1] A Friday Evening Discourse delivered on February 22, 1901, at the Royal Institution, by Sir W. Roberts-Austen, K.C.B., F.R.S. The lecture consisted mainly of a series of experiments conducted at very high temperatures, and apart from them it is difficult to give a continuous abstract of it.

[3] "Optic," pp. 316–319, quoted by Shaw in his edition of the works of Boyle, vol. ii. p. 400.

the method by which the metals are prepared. If they are in a chemically active state, as lead is which has been prepared from tartrate of lead, they will, in many cases, take fire in air and burn at the ordinary temperature. This lead burns readily when shaken in air. If this mass of uranium, for which I am indebted to M. Moissan, is filed in air, the detached particles will ignite. Metallic iron which has been reduced by hydrogen from its oxide at a temperature below 700° C. will also take fire and burn in air at the ordinary temperature, a point of extraordinary interest in relation to the allotropy of iron (Osmond and Cartaud, *Ann. des Mines*, August 1900). Metals in this chemically active state are said to be "pyrophoric."

So far as I am aware, metals in this chemically active state have not been used as fuels. Neither am I aware that any use has been made of the allotropy of metals as enabling them to be used as fuel, but Prof. Graham once told me that pyrophoric iron had been suggested for warming ladies' muffs, the intention being to place the iron in a small receptacle and to admit air gradually as warmth was needed. Sir Henry Trueman Wood also remembers the suggestion, but tells me that he can find no record of it in the *Journals* of the Society of Arts. I may just mention that the burning of metallic antimony plays a very important part in roasting silver ores, and the behaviour of the metal is so peculiar while burning that I must pause to show it you. [A melted globule of antimony, if thrown on to a tray of paper, darts about and cannons from the sides, leaving a track of dark oxide on the paper.]

The metal I am going to employ as fuel is aluminium, the oxygen for its combustion being supplied by metallic oxides, which readily part with their ogxyen to aluminium if it be raised to certain definite temperatures. This question of the transference of oxygen from one metal to another, which results in the liberation of the metal attacked, is of special interest to us at the Royal Institution, for it undoubtedly originated within these walls and is due to Sir Humphry Davy. He discovered potassium in 1807, and in 1809 attempted to remove the oxygen from alumina by heating it with metallic potassium. He says (*Phil. Trans.*, part i. 1810, p. 60), "if I had succeeded in isolating the metal I should have called it *alumium*." His success was imperfect, but he certainly did obtain, by the intervention of metallic potassium, an alloy of aluminium and iron. It remained for Wöhler to prepare pure metallic aluminium from its chloride in 1827, and for Henri Saint Claire Deville, who began to work in 1854, to establish the metallurgy of aluminium on an industrial scale. As regards the reduction of metals from their chlorides, Wöhler (*Ann. der Chemie*, vol. cvi. p. 118) obtained crystalline compounds of chromium and aluminium and Michel (*ibid.*, vol. cxv. p. 102; *ibid.*, vol. cxiii. p. 248) compounds of aluminium with manganese, iron, nickel, tungsten, molybdenum and titanium. Levy (*Comptes rendus*, vol. cvi. p. 66) obtained an alloy of titanium and aluminium, Beketoff (*Ann. der Chemie*, vol. cx. p. 374) an alloy of barium with aluminium from the chloride of barium mixed with baryta. Dr. Goldschmidt (*ibid.*, May 1898) has given references to these authorities in a recent valuable paper. In 1856, Charles and Alexandre Tissier (*Comptes rendus*, vol. xliii. 1856, p. 1187) observed the fact which is the starting point of the experiments I have to show you. They found that aluminium decomposes the oxides of lead and of copper, much heat being evolved by the reaction.

They do not appear to have used aluminium in a finely divided state, and therefore failed to reduce certain metals from their oxides which are now known to be perfectly easy to reduce. It was not until comparatively recently that the use of aluminium for separating other metals from their oxides assumed serious proportions. Claude Vautin showed on June 13, 1894, at a soirée of the Royal Society, a few metals, and among them carbon-free chromium and manganese, which he had prepared, and as he undoubtedly gave the impulse that started much of the subsequent work in this direction, it may be well to give the description which was appended to the specimens he showed. It runs as follows:

Specimens of Metallic Chromium, Manganese, Tungsten Iron, &c., free from Carbon, also fused Alumina, obtained during reduction of the metallic samples.

The specimens of metallic chromium, manganese, &c., have been reduced from their oxides by means of metallic aluminium. The oxide of the metal to be reduced is intimately mixed with finely divided aluminium, and heated in magnesia-lined crucibles. The heat produced by the oxidation of aluminium during the operation is sufficient to fuse alumina, a specimen of which is exhibited.

The subject is, however, in a sense your own, for, so far as I know, the lecture on "The Rarer Metals and their Alloys" (NATURE, May 2 and 9, 1895), which I delivered here in 1895, was the first occasion on which the reducing action of aluminium was demonstrated on a comparatively large scale, and covered an extended series of metallic oxides. Since that time great progress has been made, the most noteworthy advance being in the direction of the use of aluminium for the sake of the heat afforded by its combustion as a true fuel, the oxygen being derived, not from the air, but from a metallic oxide. In order that I may be clear, let me repeat that when coal is burnt the oxygen is derived from the air. When aluminium is used as a fuel the oxygen is derived from a metallic oxide, the metals change places, the aluminium is oxidised,

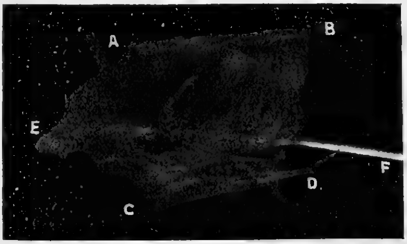

FIG. 1.—The oxidation in air of an amalgamated wire of aluminium, E F. The films of alumina, A B and C D, are those which first formed on the wire.

and the other metal set free from its oxide. This part of the subject must be carefully approached, and the question at once arises as to what extent the aluminium must be heated before it will begin to abstract oxygen from air or from an oxide. It is well known that the metal aluminium will not oxidise sensibly in the air at the ordinary temperature, but the presence of a little mercury enables it to oxidise readily. Le Bon (*Comptes rendus*, October 29, 1900, p. 707) has shown how minute the quantity of mercury may be. This wire of aluminium to which a thermo-couple is attached will, if a mere trace of mercury be rubbed on its surface, become rapidly heated by oxidation, the temperature rising to 102° C., while at the same time a fungoid-like growth of alumina forms on its surface (see Fig. 1). Aluminium foil will burn readily in oxygen if its combustion

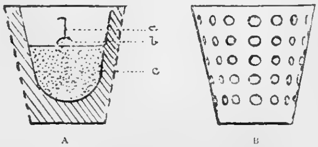

FIG. 2.—Crucible in which the reduction of metallic oxides is effected. A, diagrammatic section of the perforated sheet-iron crucible, B, lined with magnesia; *c* is the mixture of aluminium and the metallic oxide to be reduced to metal; *a* is a piece of magnesium ribbon placed in a mixture, *b*, of aluminium and some readily reducible oxide.

be started by a glowing fragment of charcoal. The temperature at which aluminium will abstract oxygen from a metallic oxide will depend on the oxide submitted to its action. Three cases may be taken: (1) Lead oxide and granulated aluminium may be ignited by a match, as may also silver oxide (Ag_2O), for it parts with its oxygen very readily. (2) Chromium oxide (Cr_2O_3) and granulated aluminium burns slowly and requires rather a high temperature to start the reaction. Oxide of iron (Fe_2O_3) and granulated aluminium also requires the presence of a readily reducible oxide to start the reaction. On the other hand, (3) a mixture of sodium peroxide, carbide of calcium and granulatedaluminium may be started by a drop of water by the mere inflammation of the acetylene. In all these cases, or in any other case, the products are solid, for if any of the reduced metal is volatilised it soon condenses, and may be collected, usually in an oxidised form.

In using aluminium as fuel the object, of course, is to produce intense heat, and returning to this mass of iron ore from the Surrey heath it may at once be stated that an oxide of iron,

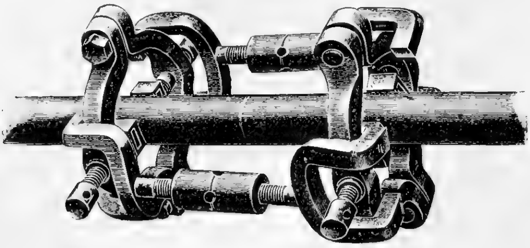

FIG. 3.—The clamps used or welding tubes up to four inches in diameter.

ferric oxide, is the most convenient oxide to use, partly because it is inexpensive.

Many of my audience already know that the recent investigations having for their object the use of aluminium as a source of heat have been conducted by Dr. Hans Goldschmidt, of Essen, and it is through his labours that metallurgy enters upon an entirely new phase. It would be difficult to offer him fuller or more unstinted praise than that. You will, I trust, soon realise how much industry is indebted to him. In its simplest form his process consists in igniting a mixture of oxide of iron, ferric oxide and finely divided aluminium. To this mixture the name of "thermit" has been given, and several varieties of it, adapted to various kinds of work, are used by Dr. Goldschmidt at the works of the Allgemeine Thermit-Gesellschaft at Essen-Ruhr.

The mixture is placed inside a crucible (Fig. 2) and is ignited by a small piece of magnesium wire, which serves as a kind of wick if it is placed in a little heap of calcium sulphate and aluminium. Such a mass will now be lighted, and you see intense heat is produced. [When the operation was conducted in accordance with the above indications, the theatre was brilliantly illuminated by the intense light produced. A mass of metallic chromium weighing about 100 lbs., reduced to the metallic state as above described, was exhibited.] The aluminium abstracts oxygen from the oxide of iron, and a sufficiently intense heat is produced, not only to melt

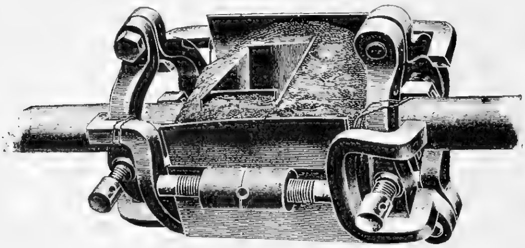

FIG. 5.—Casing packed round with moulding sand in readiness for the welding operation.

the iron which is liberated from its oxygen, but to melt up the slag and, further, to leave a considerable surplus of heat, which is available for doing other work. No known pyrometer will enable the heat to be measured. I believe it to be about 3000° C. The aluminium plays the part of a fuel, and this table shows the advantage aluminium possesses as compared with carbon for the particular work required of it.[1]

The Reduction of Fe_2O_3 *to Iron by Aluminium and by Carbon.*

	Aluminium.	Carbon.
Compound produced ...	Al_2O_3	CO
Amount of reducing agent required to produce 1 kilo. of iron ...	0·484 kilo.	0·321 kilo.
Amount of heat produced by oxidation of the reducing agent ...	3456 calories	770 calories
Heat required to reduce the Fe_2O_3	1796 ,,	1796 ,,
Heat required for fusion of the slag	548 ,,	
Heat required for fusion of iron	362 ,,	
Total heat required ...	2706 ,,	1796 ,,
Residual heat available	750 ,,	− 1026 ,,

On the aluminium side some 750 calories (units of heat) are available to do work (3456 − 2706 = 750 calories). On the carbon side there is a deficiency of no less than − 1026 calories. As regards the crucibles, they may be made of alumina, the solid product which is the result of the combustion of aluminium. They may also be made of magnesia or mended with magnesia. I shall have more to say about the solid product of the combustion subsequently. The practical

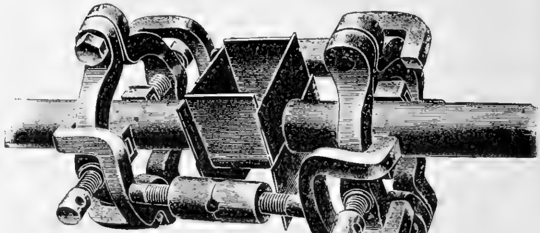

FIG. 4.—Tubes clamped together with a casing of thin iron round the junction to be welded.

application of the process is as follows. The ignited and molten mass in the crucible is so intensely hot that it may be made to unite surfaces of steel that require to be joined, such as the ends of lengths of rails. If I may use a simile which enables me to describe the method rapidly, the fluid contents of the crucible are applied as a hot bandage might be applied to wounded or severed surfaces in the human body which require medical treatment to facilitate healing or to cause them to unite. It may be objected that the fluid contents of the crucible would set as a whole round the metallic junction and give trouble, but this is not the case, for a layer of fluid alumina appears both to coat the rod, tube or rail which has to be welded, and to set in a mass which can be readily detached after the work is done. The casings (Figs. 4 and 5) are protected in the same way. The diagrams (Figs. 3, 4, 5) need but little comment, as they sufficiently indicate the method adopted in the case they represent. These figures were used to illustrate a paper by Mr. E. F. Lange (*Journal* of the Iron and Steel Institute, 1900, No. ii. p. 191). [I was indebted to him for the loan of small appliances of a similar kind to enable me to demonstrate to the audience the welding of steel tubes, and the operation was shown on as large a scale as safety would

[1] These data are from a paper by Prof. Kupelwieser, of Leoben, *Oesterreichische Zeitschrift für Berg- und Huttenwesen*, vol. xlvii. 1899, p. 145–149.

permit.] The welding of three miles of electrical tramway rails was successfully effected in Brunswick in May 1900.

As regards the comparison of the use of aluminium as fuel with the electric arc, M. Camille Matignon (*Moniteur Scientifique Quesneville*, No. 702, Juin 1900, p. 357 *et seq.*), in a very interesting discourse recently delivered in Paris, has instituted a comparison between the Goldschmidt process and the electric furnace. Quoting Moissan ("Le Four électrique," p. 19), he shows that in reducing titanic acid by carbon in the electric furnace having a "laboratory space" of 800 cubic centimetres, 300 horse-power absolute were employed, producing per second 190,500 calories by burning 1·08 kilograms of aluminium. On the other hand, by burning 3·2 kilograms of ferric oxide during one minute in a crucible of about the same

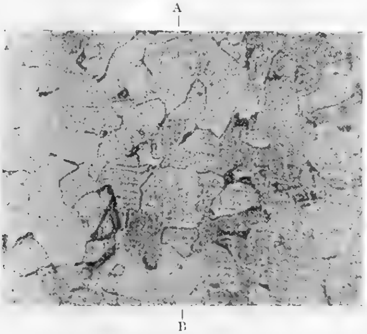

FIG 6.—Section of the welded test piece (Fig. 7), showing crystals passing across the line of weld, A B. Magnification 140 diameters.

capacity as the laboratory of the electric furnace, the rate of evolution of heat is equivalent to 375 horse-power absolute; the latter process does not, however, work continuously, but could readily be made to do so. It should be pointed out that an impure variety of aluminium can be used, and that if the heat needed to effect a given operation is but moderate, the aluminium may be diluted by the presence of an inert substance.

The photomicrograph (Fig. 6) is from a little test piece of wrought iron (Fig. 7) which was cut in two. The carefully faced surfaces were then clamped together, and I united them into an excellent weld, without any previous experience in conducting such an operation. No line of demarcation can be seen, and the crystals pass over the line A B, which I know by measurement to be that of the actual weld.

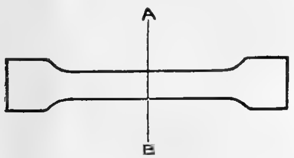

FIG. 7.—Test piece of wrought iron welded at A B. See Fig. 6 for micro-section.

The very hot molten iron may be used in a somewhat different way for repairing defective castings. In this case the slag is carefully poured off the fluid iron in the crucible and the iron is then poured into the defective part in the casting which it is required to mend, a guiding rim of some refractory material being provided. By mixing other metallic oxides with the iron oxide, the metals they contain are reduced and alloy themselves with the iron, and the composition of the defective casting can thus be matched. In connection with the repairs of fractured or defective steel castings, the possibility of producing directly steel of a suitable degree of carburisation is important. This may readily be effected by mixing fragments of cast iron with the "thermit," thus 70 to 90 grammes of cast iron mixed with 1000 grammes of thermit gives a very fine-grained and workable steel. One useful application of the process is for locally softening hardened armour plates in the positions where the bolts and screws have to be inserted through the holes drilled to admit them. This is effected by placing a little fluid "thermit" on the spot where the plate has to be drilled and the heat softens the hardened surface. It should also be remembered that, with reference to the repairs of defective parts of machinery, a suitable admixture of metallic oxides with the ferric oxide, such as those of chromium, nickel or manganese, may be reduced together with the iron derived from the ferric oxide. Richly carburised iron may be added to the molten mass, and in this way any quality of steel may be produced.

This latter reference to metallic oxides reminds us of the original use for which the finely divided aluminium was employed, namely, as a reducing agent for the rarer metals and not for the sake of the heat evolved by the reaction. This portion of the subject I dealt with at the Royal Institution six years ago, but there have been great advances since. It would have been tedious to have conducted the experiments before you, as the crucibles would have taken so long to cool; but in each of these crucibles, which will now be broken open, I hope to find a small mass of metal, which, until now, has not left the spot in which it was reduced. [About a pound of nickel and a pound of cobalt were then produced from the respective crucibles in which they had been reduced].

Manganese and chromium containing only small quantities of carbon are now produced on a large scale for industrial use. As regards the reduction of metals and alloys from their oxides by burning aluminium, the following are the most recent results that have been obtained (*Stahl und Eisen*, March 24, 1901). The use of carbon-free chromium in connection with the metallurgy of steel is an exceedingly useful development of the methods we have considered. Hitherto, the addition of ferro-chrome to steel has involved a loss of from 20 to 25 per cent. of the chromium, while with pure chromium the loss is slight. Moreover, the addition of ferro-chrome incidentally raises the percentage of carbon, and steel containing, for instance, 2·5 per cent. of chromium should not have more than from 0·15 to 0·20 per cent. of carbon, and this can only be attained by the use of pure chromium. In the manufacture, also, of tool steel, the percentage of chromium may reach from 6 to 10 per cent. and even higher, a result which is only rendered possible by the use of pure chromium. In the same way, in connection with the metallurgy of copper, the possibility of providing carbon-free manganese is important, as is also the preparation of cupro-manganese free from iron. Alloys of manganese with zinc and with tin are likely to prove of value. Many uses have been found for the alloy containing 80 per cent. of zinc and 20 per cent. of manganese, while it is anticipated that the alloy containing 50 per cent. of tin and 50 per cent. of manganese will also prove to be important. Use has also been found for an alloy of 70 per cent. manganese and 30 per cent. chromium. Ferro-titanium, with 20 to 25 per cent. of titanium, and alloys of titanium and manganese containing from 30 to 35 per cent. of titanium, have also been produced. Titanium, moreover, absorbs nitrogen, and ferro-titanium is found to be very useful in producing sound steel castings. I, quite independently of Dr. Goldschmidt, succeeded in the preparation of alloys of iron with from 3 to 25 per cent. of boron, the alloy containing 3 per cent. of boron proving to be beautifully crystallised. Dr. Goldschmidt states that definite results have not been obtained in attempts to utilise it. I am still investigating this most interesting subject. Dr. Goldschmidt has obtained ferro-vanadium, the best results being given with steel containing 0·5 per cent. of vanadium. He has also prepared an alloy of lead and barium containing 30 per cent. of barium, which affords an example of the possibility of forming alloys of metals with those of the alkaline earths by this process.

It only remains for me to direct your attention to the nature of the solid product of the combustion of aluminium, which is alumina often of a high degree of purity, and in a specially interesting form. The alumina from the reduction of oxide of chromium, when it is allowed to cool, forms large ruby-tinted crystalline masses, closely resembling the natural ruby. I have now to show you on the screen some rubies and sapphires produced as an incident of this beautiful process. The blue sapphire mass is, however, only translucent, not transparent. The ruby crystals are often very beautiful, as these slides show. Rubies placed in a vacuum tube and subjected to the bombardment of an electric discharge are, as Sir William Crookes has taught us, beautifully phosphorescent. I have here in this tube some thin crystalline plates of artificial ruby; they become beautifully phosphorescent when the current from the induction coil is passed through the tube, and by the kindness of Sir William Crookes I can show you some true rubies treated in a similar way. The behaviour of the artificial rubies in the vacuum tube is not quite as brilliant as that of the natural ones, but hitherto no special attention has been devoted to their preparation; they are simply thin plates broken from a large crystalline mass of slag such as that on the table. I may add that this variety of corundum produced by the burning of aluminium is very hard, and may be used, not only for the same purposes as ordinary corundum, but for lining the crucible in which the operations are conducted, so that the product of combustion takes its place in conducting the process. My warmest thanks are due to Dr. Goldschmidt for lending me the beautiful specimens on the table, and to Mr. W. H. Merrett for his aid in conducting the experiments.

I have set before you the considerations respecting the use of metals as fuel simply as they appear to flow. I trust that the adoption of the title of this lecture has been justified by the evidence given as to the possibility of using metals as fuel in the strictest sense of the word. It is well to be accurate on this point because we are told that the first known appearance of the word "fuel" in the English language occurs in a poem (*Coeur de Lion*, 15th century), and seems to have been a misinterpretation of the old French word *fouaille*, and was adopted in the belief that sustenance for the body and food for the flames are synonymous. Widening our view of metals by grouping them with fuels will be acceptable because fire and flame powerfully appeal to our thoughts. We "kindle" enthusiasm, and add "fuel" to the fire of ambition, in fact we constantly use fire, flame and fuel as similes, and any prospect of extending their use to us as such by enlisting metals in the service will be welcome. An early Italian metallurgist, Vanoccio Biringuccio, might not have thought so, for I find that, writing in the sixteenth century, he quaintly devotes the last chapter of a work on metallurgy to "Fires which burn and leave no ashes."[1] In this chapter he appeals to envy, hatred, malice and other products of a kindled imagination, and traces their analogies to fuel and flame, but he speedily takes leave of his readers in alarm at the prospect such a treatment of the subject presents.

The burning of aluminium as fuel gives us sapphires and rubies in the place of ashes, and metallic fuel is burnt, not by the air above, but by the oxygen derived from the earth beneath, as it occurs in the red and yellow oxides to which our rocks and cliffs owe their colour and their beauty.

AGRICULTURAL EXPERIMENTS.

A NUMBER of reports on agricultural experiments conducted by provincial colleges have reached us, of which the most comprehensive is that issued by the Agricultural Department of the Durham College of Science. Most of the field-work that this report deals with was planned and started by Prof. Middleton's predecessor, and the results are becoming more valuable each year. It is a report that should be in the hands of every one that is interested in agricultural progress, though no one need expect to find it light reading.

In the north of England, as in many other parts of the country, the turnip crop suffers severely from finger and toe, and the work of the Durham College of Science is throwing much fresh light on this subject. Hitherto the disease has chiefly been combated by the application of large dressings of slaked lime applied a year or less before it was intended to grow a cruciferous crop. In this way the fungus and its spores are destroyed more or less effectively, but at a larger cost than agriculture can now well bear. It appeared, however, that if lime can get rid of the disease when the substance is applied only a short time before the crop that the fungus affects is to be grown, the clearance of the soil will be much more effectual—or will be accomplished at less outlay—if the trouble is attacked at its fountainhead, namely, directly after an infected crop has been grown. With this object in view, a field that had grown a much-diseased crop in 1896 was divided into five plots in the autumn of that year, one of the plots being soon afterwards treated with 2½ tons per acre of ordinary burned lime, while another plot did not receive its dressing till the autumn of 1899. Following the four-course shift the field was again under turnips in 1900, with the following result per acre:—

	Weight of roots				Percentage	
	Sound		Diseased		Diseased and destroyed	Sound
	Tons	cwt.	Tons	cwt.		
No lime	13	18	2	17	41·6	58·4
Lime applied, Feb. 1897...	20	11	0	13	10·1	89·9
,, ,, Nov. 1899...	15	12	1	13	29·2	70·8

The above figures hardly put the case so strongly as they might, for whereas when the roots were diseased to the extent of 41·6 per cent. and 29·2 per cent., such roots were practically valueless, the infected roots were far from the putrescent stage when the percentage of disease was 10·1.

The now well-known Cockle Park experiments on "manuring for mutton" are described at length in the above report, and are popularly presented in a circular issued by the Northumberland County Council. In this circular the results for each plot are shown by a diagrammatic sheep, the sections of whose body represent (*a*) the growth due to the soil in its unimproved condition; (*b*) the growth induced by manurial treatment; and (*c*) the portion of such growth as is needed to cover the manurial outlay. So far a large dressing of basic slag applied four years ago, and not repeated, has proved most effective; whereas the lowest place is taken by a moderate dressing of lime. A corresponding circular deals with the experiments on turnip manuring.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A WELL-ARRANGED calendar of the Merchant Venturers' Technical College, Bristol, showing the courses of work to be taken in the forthcoming session and the facilities for study, has been received. At the end of each syllabus a useful list of books of reference is given, in addition to the usual list of text-books. We assume that the reference books recommended are to be found in the school library, or on the laboratory bookshelf.

A VACATION course of lectures and observations connected with nature study, for teachers in rural schools, was opened at the Harper-Adams Agricultural College, Newport, Salop, on August 1 with an address by the principal, Mr. P. Hedworth Foulkes. The primary object of nature teaching is, he pointed out, to encourage and promote in children the power of observation, so that when the school days are over the pupil is in full and complete sympathy with natural knowledge, and takes an intelligent interest in it. The course has been arranged to help teachers who are desirous of cultivating this spirit of observation and inquiry in their pupils.

PROF. W. J. ASHLEY, now one of the professors of economics in the Harvard University, Cambridge, Massachusetts, has been appointed to the first or organising chair of the future faculty of commerce in the University of Birmingham. Prof. Ashley was a Brackenbury scholar at Balliol College, Oxford, and obtained a first in history in 1881, followed by a fellowship of Lincoln College. For three years he was college tutor in Oxford, lecturing in large classes in economics and history. Towards the end of the eighties he was called to a chair of economics at Toronto, and after a short time the staff of Harvard University went out of the ordinary course to enable provision to be made among them for him, and there he has occupied the chair of economic history since 1892, the chair of economics itself being held by Prof. Taussig. It is understood to be the wish of the council and senate of the University of Birmingham that the professor should devote his first year to investigation and consolidation of ideas, in consultation with men of business in this and other countries,

[1] "De la Pirotechnia," 1540, p. 167. (Venice). "*Del fuocho che consuma et non facenere.*"

and that the faculty of commerce should not be constituted, or regular teaching begin, until the following session.

THE Royal Commissioners for the Exhibition of 1851 have made the following appointments to science research scholarships for the year 1901, on the recommendation of the authorities of the several universities and colleges. The scholarships are of the value of 150*l*. a year, and are ordinarily tenable for two years (subject to a satisfactory report at the end of the first year) in any university at home or abroad, or in some other institution approved of by the Commissioners. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country:—J. A. Craw, University of Glasgow; F. Horton, University of Birmingham; A. Slator, University of Birmingham; R. B. Denison, Yorkshire College, Leeds; G. Owen, University College, Liverpool; G. Senter, University College, London; F. W. Rixon, Owens College, Manchester; T. Baker, Durham College of Science, Newcastle-on-Tyne; S. C. Laws, University College, Nottingham; Alice E. Smith, University College of North Wales, Bangor; J. Hawthorne, Queen's College, Belfast; R. K. McClung, McGill University, Montreal; C. W. Dickson, Queen's University, Kingston, Ontario; G. Harker, University of Sydney; Dr. J. M. Maclaren, University of New Zealand. The following scholarships granted in 1900 have been continued for a second year on receipt of a satisfactory report of work done during the first year:—C. E. Fawsitt, University of Edinburgh; V. J. Blyth, University of Glasgow; J. Moir, University of Aberdeen; Dr. W. M. Varley, Yorkshire College, Leeds; J. C. W. Humfrey, University College, Liverpool; S. Smiles, University College, London; Alice L. Embleton, University College of South Wales and Monmouthshire, Cardiff; J. A Cunningham, Royal College of Science, Dublin; W. S. Mills, Queen's College, Galway; J. Patterson, University of Toronto; W. C. Baker, Queen's University, Kingston, Ontario; J. Barnes, Dalhousie University, Halifax, Nova Scotia; J. J. E. Durack, University of Sydney. The following scholarships granted in 1898 and 1899 have been exceptionally renewed for a third year:—L. N. G. Filon, University College, London; J. W. Mellor, University of New Zealand; F. W. Skirrow, Yorkshire College, Leeds; C. G. Barkla, University College, Liverpool; W. Campbell, Durham College of Science, Newcastle-upon-Tyne; L. Lownds, University College, Nottingham; Dr. J. T. Jenkins, University College of Wales, Aberystwyth; R. D. Abell, University College of North Wales, Bangor; B. D. Steele, University of Melbourne.

SCIENTIFIC SERIAL.

American Journal of Science, July.—Geology of the Shonkin Sag and Palisade Butte Laccoliths in the Highwood Mountains of Montana, by W. H. Weed and L. V. Pirsson.—On the manganese ore deposits of the Queluz (Lafayette) district, Minas Geraes, Brazil, by O. A. Derby.—On the bituminous deposits situated at the south and east of Cardenas, Cuba, by H. E. Peckham. On the north of Cuba there is a tract of country more than 4500 square miles in area, the springs and wells of which give indications of the existence of liquid bitumens of varying density. The oil which has been obtained resembles the oils of Russia, but it is doubtful if, in view of the enormous production which recent developments in Texas and Indiana promise, there is at present any encouragement for even experimental drilling in Cuba.—Mineralogical notes, No. 2, by A. F. Rogers. A description of new types of calcite and galena, together with a note of new localities for some rare minerals.—A new solution for the copper voltameter, by W. K. Shepard. A saturated solution of copper sulphate is boiled for a short time to expel the air and then kept for about an hour at 100° C. in contact with metallic copper in order to neutralise the solution. About ·05 per cent. of ammonium chloride was then added. Using this solution it was found that the weight of copper was practically independent of the temperature between 20° and 40° C; the solution may be used a large number of times, and the results are independent of the current density between the limits of ·02 and ·07 ampere per square centimetre.—The thermomagnetic and galvanomagnetic effects in tellurium, by M. G. Lloyd.—Additions to the avifauna of the Bermudas, with diagnoses of two new subspecies, by A. H. Verrill.—The induced alternating current discharge studied with reference to its spectrum and especially its ultra-violet spectrum, by A. W. Wright and E. S. Downs.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 23.—"Preliminary Statement on the Prothalli of *Ophioglossum pendulum* (L.), *Helminthostachys zeylanica* (Hook), and *Psilotum*, sp." By William H. Lang, M.B., D.Sc., Communicated by Prof. F. O. Bower F.R.S.

During a recent visit to Ceylon and the Malay Peninsula, the author found prothalli of *Ophioglossum pendulum* and *Helminthostachys zeylanica* as well as a single specimen, which there is reason to regard as the prothallus of *Psilotum*. This paper gives a brief account of the mode of occurrence and external form of these three prothalli.

Ophioglossum pendulum. The prothalli were found in the humus collected by an epiphytic fern. They were wholly saprophytic, devoid of chlorophyll and of a yellowish-white colour. An endophytic mycorhiza is present in them. The prothallus is radially symmetrical, the older ones consisting of a number of short cylindrical branches radiating in all directions into the humus. The surface of these branches is covered with short unicellular hairs (paraphyses); rhizoids are absent. The antheridia and archegonia, which occur on the same prothallus, resemble those of *O. pedunculosum*.

Helminthostachys zeylanica. The wholly saprophytic prothalli of this plant occur about two inches below the surface of the ground. They are radially symmetrical; the lower vegetative half, in which is an endophytic fungus, is more or less lobed and bears rhizoids. The sexual organs are borne on the upper half; the antheridia are large and sunk beneath the surface; the archegonia project slightly from it. Sometimes the prothalli are monœcious, but more often a prothallus bears antheridia or archegonia only. The ternate lamina of the first leaf of the young plant is green and appears above ground.

Psilotum. A single prothallus, presumably belonging to this plant, was found embedded among the roots covering the stem of a tree-fern. It was one-quarter of an inch long and presented a general resemblance to some prothalli of *Lycopodium*, having a well-marked primary tubercle. The sexual organs were borne on the overhanging margin of the upper region of the prothallus, between which and the lower vegetative region the meristem will probably be found to be situated.

June 20.—"The Mechanism of the Electric Arc." By (Mrs.) Hertha Ayrton. Communicated by Prof. Perry, F.R.S.

The object of the paper is to show that, by applying the ordinary laws of resistance, of heating and cooling and of burning to the arc, considered as a gap in a circuit furnishing its own conductor by the volatilisation of its own material, all its principal phenomena can be accounted for, without the aid of a large back E.M.F., or of a "negative resistance," or of any other unusual attribute.

The Apparent Large Back E.M.F.

It is shown how volatilisation may begin, even without the self-induction to which the starting of an arc, when a circuit is broken, is usually attributed; and it is pointed out that, when the carbons are once separated, all the material in the gap cannot retain its high temperature. The air must cool some of it into carbon *mist* or *fog*, just as the steam issuing from a kettle is cooled into water mist at a short distance from its mouth. The dissimilar action of the poles common to so many electric phenomena displays itself in the arc at this point. Instead of *both* poles volatilising the *positive* pole alone does. It is considered, therefore, that the arc consists of (1) a thin layer of carbon vapour issuing from the end of the positive carbon, (2) a bulb of carbon mist joining this to the negative carbon, and (3) a sheath of burning gases, formed by the burning of the mist, and the hot ends of the carbons, and surrounding both. The vapour appears to be indicated in images of the arc by a sort of gap between the arc and the positive carbon, the mist by a purple bulb and the gases by a green flame.

The flame is found to be practically insulating, so that nearly the whole of the current flows through the vapour and mist alone. It is suggested that the vapour has a high specific resistance compared with that of the mist, and that it is to the great resistance of this vapour-film that the high temperature of the crater is due, and not to any large back E.M.F. of which it is the seat.

Volatilisation can only take place at the surface of contact between the vapour-film and the positive carbon. When that surface is smaller than the cross-section of the end of the carbon it must dig down into the solid carbon and make a pit. The sides of the pit, however, must be hot enough to burn away where the air reaches them, hence there is a race between the volatilisation of the centre of the carbon and the burning of its sides that determines the shape of the carbon. When the arc is short, the air cannot get so easily to the sides of the pit, hence it remains concave. When the arc is long, the burning of the sides gains over the volatilisation of the centre, and the surface of volatilisation becomes flat, or even slightly convex.

The peculiar shaping of the negative carbon is shown to be due to its tip being protected from the air by the mist and its sides being burnt away under the double action of radiation from the vapour film and conduction from the mist, to a greater or less distance, according to the length of the arc and the cross-section of the vapour-film.

It is shown that if the crater be defined as being that part of the positive carbon that is far brighter than the rest, then the crater must be larger, with the same current, the longer the arc, although the area of the volatilising surface is *constant* for a constant current.

By considering how the cross-section of the vapour-film must vary with the current and the length of the arc, it is found that its resistance f must be given by the formula

$$f = \frac{h}{A} + \frac{k+ml}{A^2},$$

where h, k and m are constants, l is the length of the arc, and A the current. This is the same form as was found by measuring the P.D. between the positive carbon and the arc by means of an exploring carbon and dividing the results by the corresponding currents. Hence the existence of a thin film of high-resisting vapour in contact with the crater would not only cause a large fall of potential between the positive carbon and the arc, exactly as if the crater were the seat of a large back E.M.F., but it would cause that P.D. to vary with the current and the length of the arc exactly as it has been found to vary by actual measurement.

The Apparent "Negative Resistance."

As nearly all the current flows through the vapour and mist, the surrounding flame being practically an insulator, the resistance of a solid carbon arc, apart from that of the vapour, must depend entirely on the cross-section of the mist. To see how this varies with the current, images of an arc of 2 mm. were drawn, with the purple part—the mist—very carefully defined, for currents of 4, 6, 8, 10, 12 and 14 amperes. The mean cross-section of the mist was found to increase more rapidly than the current, consequently its resistance diminishes more rapidly than the current increases. As the formula for the resistance of the vapour film shows that it too diminishes faster than the current increases, it follows that the whole resistance of the arc does the same, and that consequently the P.D. must diminish as the current increases. Hence if δV and δA be corresponding increments of P.D. and current, $\delta V/\delta A$ must be negative, although the resistance of the arc is positive.

It is found, from the above measurements of the cross-sections of the mist, that the connection between m, the resistance of the mist, and the current, is of the form,

$$m = \frac{\alpha}{A} + \frac{\beta}{A^2}.$$

If m varies directly with the length of the arc, then

$$m = \left(\frac{\alpha}{A} + \frac{\beta}{A^2}\right) l.$$

Adding this equation to (1), we get

$$f + m = r = \frac{p+ql}{A} + \frac{s+tl}{A^2}$$

for the whole resistance of the arc, which is exactly the form that was found by dividing direct measurements of the P.D. between the carbons by the corresponding currents. Hence there is no reason why this ratio should not represent the *true* resistance of the arc.

Under what circumstances $\delta V/\delta A$ *measures the True Resistance of the Arc.*

When the current is changed it takes some time for the vapour film to alter its area to its fullest extent, and still more time for the carbon ends to change their shapes. All the time these changes are going on the resistance of the arc, and, consequently, the P.D. between the carbons, must be altering also. Both these, therefore, depend, not only on the current and the length of the arc, but also, till everything has become steady again, *i.e.* till the arc is "normal" again, on how lately a change has been made in either. At the first instant after a change of current, before the volatilising area has had time to alter at all, δV and δA must have the same sign, just as they would if the arc were a wire, but as the volatilising surface alters, the sign of δV changes. If, therefore, a small alternating current is applied to the direct current of an arc, it will depend on the frequency of that current whether $\delta V/\delta A$ is positive or negative. When the frequency is so high that the volatilising surface never changes at all, $\delta V/\delta A$ will measure the true resistance of the arc unless it has a back E.M.F. which varies with the alternating current.

The measurements of the true resistance of the arc made in this way by various experimenters have given very various results, because probably the frequency of the alternating currents employed has been too low not to alter the resistance of the arc. A curve is drawn showing how the value of $\delta V/\delta A$ with the same direct current and length of arc varies with the frequency of the alternating current, and it is pointed out that even if the arc has as large a back E.M.F. as is usually supposed, the *true* resistance cannot be measured with an alternating current of lower frequency than 7000 complete alternations per second.

The exact conditions under which the *true* resistance of the arc can be measured in this way are examined, and the precautions that it is necessary to take to ensure the fulfilment of these conditions are enumerated.

The Changes introduced into the Resistance of the Arc by the Use of Cored Carbons.

A core in either or both carbons has a great effect on both the P.D between the carbons and the *change* of P.D. that accompanies a given *change* current. It lowers the first and makes the second more positive, *i.e.* gives it a smaller negative or larger positive value, as the case may be. It is pointed out that this might be due to the influence of cores either on the cross-section of the arc or on its specific resistance, or on both.

To see the effect on the cross-section, enlarged images were drawn of 2 mm. arcs with currents increasing by 2 amperes from 2 to 14 amperes, between four pairs of carbons, + solid − solid, + solid − cored, + cored − solid, + cored − cored. Two sets of images were drawn with each pair of carbons—the one immediately after a change of current, to get the "non-normal" change, and the other after the arc had become normal again. The mean cross-section of the mist was calculated in each case, and its cross-section where it touched the crater was taken to be a rough measure of the cross-section of the vapour film.

It was found that the mean cross-section of the mist with a given current was largest when both carbons were solid, less when the negative carbon alone was cored, less still when the positive alone was cored, and least when both were cored. Coring either the positive carbon alone, or both carbons, had the same effect on the cross-section of the vapour film as on that of the mist, but coring the negative alone only diminished this cross-section immediately after a change of current, but not when the arc had become normal again. Hence it was deduced that if the cores altered the *cross-sections* of the arc only they would *increase* its resistance, and, consequently, the P.D. between the carbons. As they *lower* this, however, they must do it by lowering the specific resistance of the arc more than they increase its cross-section. The vapour and mist of the core must therefore have lower specific resistances than the vapour and mist of the solid carbon.

When it is the positive carbon that is cored, all the vapour and mist come from the *cored* carbon. When the negative, they come from the *uncored* carbon, and it is only because the metallic salts in the core have a lower temperature of volatilisation than carbon that the mist is able to volatilise these and so lower its own specific resistance.

The effect of a core in either carbon, or in both, must depend on the current, because the larger the current the more solid carbon will the volatilising surface cover, and the less, therefore, will the specific resistances of the mist and vapour be lowered. The way in which the core acts in each case is traced, and the alterations in the specific resistances and cross-sections due to the core are shown to bring about changes in the P.D. exactly similar to those found by actual measurements of the P.D. between the carbons. It is shown, for instance, how these changes entirely account for the fact established by Prof. Ayrton (Electrical Congress at Chicago, 1893) that, with a constant length of arc, while the P.D. diminishes continuously as the current increases, when both carbons are solid, it sometimes remains constant over a wide range of current, or even increases again, after having diminished, when the positive carbon is cored.

The alterations in the value of $\delta V/\delta A$ introduced by the cores are next discussed, and it is shown that the changes in the resistance of the arcs that *must* follow the observed changes in its cross-section, coupled with the alterations that must ensue from the lowering of its specific resistance, would modify $\delta V/\delta A$ just in the way that Messrs. Frith and Rodgers ("The Resistance of the Electric Arc," *Phil. Mag.* 1896, vol. xlii. p. 407) found that it was modified by direct measurement. Thus all the principal phenomena of the arc, with cored and with solid carbons alike, may be attributable to such variations in the specific resistances of the materials in the gap as it has been shown *must* exist, together with the variations in the cross-sections of the arc that have been observed to take place. Hence it is superfluous to imagine either a large back E.M.F. or a "negative resistance."

"The Nature and Origin of the Poison oι *Lotus arabicus*." By Wyndham R. Dunstan, M.A., F.R.S., Director of the Scientific and Technical Department of the Imperial Institute, and T. A. Henry, B.Sc., Salters' Company's Research Fellow in the Laboratories of the Imperial Institute.

The authors have already given a preliminary account (*Roy. Soc. Proc.*, vol. lxvii. p. 224, 1900) of this investigation and have shown that the poisonous property of this Egyptian vetch is due to the prussic acid which is formed when the plant is crushed with water, owing to the hydrolytic action of an enzyme, *lotase*, on a glucoside, *lotusin*, which is broken up into hydrocyanic acid, dextrose and lotoflavin, a yellow colouring matter.

The authors have continued the investigation with the object of ascertaining the properties and chemical constitution of lotoflavin and of lotusin, and also of studying the properties of lotase in relation to those of other hydrolytic enzymes.

Lotusin.

Lotusin can be separated from an alcoholic extract of the plant by a tedious process giving a very small yield, about 0·025 per cent.

Lotusin is a yellow crystalline glucoside, more soluble in alcohol than in water. When heated it gradually decomposes without exhibiting any fixed melting point. Combustions of specially purified material gave numbers agreeing with those deduced from the formula $C_{28}H_{31}NO_{16}$.

In the preliminary notice the formula $C_{22}H_{19}NO_{10}$ was provisionally assigned to lotusin on the assumption that one molecule of dextrose is formed by its hydrolysis. The formula given above, as the result of ultimate analysis, is confirmed by the observation that two molecules of dextrose are produced by acid hydrolysis, which is therefore represented by the equation—

$$\underset{\text{Lotusin.}}{C_{23}H_{31}NO_{16}} + 2H_2O = \underset{\text{Dextrose.}}{2C_6H_{12}O_6} + \underset{\text{Prussic acid.}}{HCN} + \underset{\text{Lotoflavin.}}{C_{15}H_{10}O_6}.$$

When a solution or lotusin is warmed with dilute hydrochloric acid, hydrolysis readily occurs. The liquid acquires a strong odour of hydrocyanic acid and a yellow crystalline precipitate of lotoflavin is thrown down, whilst the solution strongly reduces Fehling's solution. Dilute sulphuric acid only very slowly effects the hydrolysis of lotusin.

When warmed with aqueous alkalis, lotusin is gradually decomposed, ammonia being evolved and an acid formed to which the name *lotusinic acid* has been given.

$$C_{28}H_{31}O_{16} + 2H_2O = C_{29}H_{32}O_{18} + NH_3.$$

Lotusinic acid is a monobasic acid furnishing yellow crystalline salts. It is readily hydrolysed by dilute acids forming latoflavin, dextrose and heptogluconic acid (dextrose-carboxylic acid):

$$\underset{\text{Lotusinic acid.}}{C_{28}H_{32}O_{18}} + 2H_2O = \underset{\text{Lotoflavin.}}{C_{15}H_{10}O_6} + \underset{\text{Dextrose.}}{C_6H_{12}O_6} + \underset{\text{Heptogluconic acid.}}{C_7H_{14}O_8}.$$

With the exception of amygdalin, lotusin is the only glucoside definitely known which furnishes prussic acid as a decomposition product.

Lotoflavin.

Lotoflavin is a yellow crystalline colouring matter readily dissolved by alcohol or by hot glacial acetic acid, and also by aqueous alkalis forming bright yellow solutions. It is always present to some extent in the plants, especially in old plants. Ultimate analysis leads to the formula $C_{15}H_{10}O_6$. It is therefore isomeric with luteolin, the yellow colouring matter of *Reseda luteola*, and with *fisetin*, the yellow colouring from young fustic, *Rhus cotinus*. *Morin*, from *Morus tinctoria*, appears to be hydroxylotoflavin.

Lotoflavin does not form compounds with mineral acids. It furnishes a tetracetyl derivative and two isomeric mutually convertible trimethyl ethers which are capable of forming one and the same acetyl-trimethyl-lotoflavin. By the action of fused potash lotoflavin is converted into phloroglucin and β-resorcylic acid.

Dextrose.

The sugar resulting from hydrolysis has been found to correspond in all properties with ordinary dextrose.

Hydrocyanic acid.

The amount of prussic acid given by plants at different stages of growth has been ascertained. Mature plants bearing seed-pods have furnished 0·345 per cent. of this acid, calculated on the air-dried material which corresponds with 5·23 per cent. of lotusin. Younger plants bearing flower buds gave 0·25 per cent., whilst still smaller quantities were furnished by very young plants and hardly any by quite old plants from which the seeds had fallen.

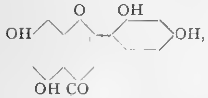
The formation of the poison, therefore, seems to reach its maximum at about the seeding period, and after this period to diminish rapidly. The Arabs are aware that the plant is safe to use as a fodder when the seeds are quite ripe, but not before. We have found that it is the lotusin which disappears during the ripening of the seeds. Old plants contain some lotase and lotoflavin, but little or no lotusin.

Lotase.

In its general properties lotase resembles other hydrolytic enzymes, from which, however, it differs in several important respects. It may be compared with emulsin, the enzyme of bitter almonds. Emulsin, however, only attacks lotusin very slowly, whilst lotase has but a feeble action on amygdalin, the glucoside of bitter almonds. Lotase is much more readily injured and deprived of its hydrolytic power than emulsin. On this account it is difficult to isolate in the solid state. Its power is not only rapidly abolished by heat, but is also gradually destroyed by contact with alcohol or glycerine. Besides lotase, the plant contains an amylolytic and a proteolytic enzyme.

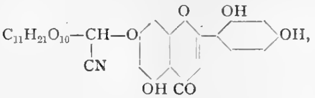
Constitution of Lotoflavin and Lotusin.

Having regard to its reactions and especially to the production, by the action of fused alkali, of β-resorcylic acid and phloroglucin, the authors conclude that lotoflavin should be represented by the formula



which is that of a compound belonging to the same class, of phenylated pheno-γ-pyrones, as its isomerides luteolin and fisetin. The peculiarity shown by lotoflavin of containing four hydroxyl groups, but furnishing only a *tri*methyl ether, is accounted for by one of the hydroxyl groups being in the ortho position to a carbonyl group.

The reactions of lotusin are best represented by the formula :



which is that of a lotoflavin ether of maltose-cyanhydrin.

This formula satisfactorily accounts for the partial hydrolysis of the glucoside by alkalis giving lotusinic acid and ammonia, and for the decomposition of the substance by acids giving lotoflavin and maltose-carboxylic acid, which is immediately decomposed into dextrose and heptogluconic acid. It also accounts for the hydrolysis of lotusin, by acids, into lotoflavin and maltose, which is further changed to dextrose.

In order to definitely localise the position of the cyanogen group in lotusin, the behaviour of several cyanhydrins of known constitution have been examined with reference to the question as to whether they would furnish hydrocyanic acid when acted on by dilute hydrochloric acid. It was found that mandelic nitrile, lævulose cyanhydrin and pentacetyl gluconitrile, in which the cyanogen group is known to occupy a position similar to that assumed for it in the formula suggested for lotusin, are, like lotusin, easily decomposed by dilute hydrochloric acid forming prussic acid and the corresponding aldehyde or ketone.

The authors wish again to express their obligations to Mr. Ernest A. Floyer, of Cairo, Member of the Egyptian Institute, who has spared neither trouble nor expense in collecting in Egypt, and despatching to this country, the material required for this investigation.

An experimental study by a photographic method of the wave figures produced on the surface of liquids contained in vessels of different forms.—On the radio-activity of radium salts, by MM. P. Curie and A. Debierne. A study of the conditions under which a radio-active salt can impart active properties to water. A solution of a radium salt exposed in an open vessel steadily loses its active properties, the rate of loss being proportional to the surface exposed to the air. But if this solution is kept in a sealed tube it gradually acquires its original activity.—A geographical demonstration of the terrestrial origin of the polar aurora, by M. Henri Stassano. All the facts cited are in accord with the theory of De la Rive.—On the continuity of the spectra due to solids and to incandescent liquids, by M. L. Décombe.—On the electrocapillary action of molecules not dissociated into ions, by M. Gouy.—On the solubility of mixtures of sulphate of copper and sulphate of soda, by MM. Massol and Maldès. Solutions obtained with a mixture of the sulphates of soda and copper, the two salts being in excess, possess an invariable composition at ordinary temperatures, but if the temperatures are sufficiently high to produce the anhydrous modification of sodium sulphate, the composition of the solution varies with the relative proportion of the two salts present.—On the chloride of neo-didymium, by M. Camille Matignon. Details are given of a simple method of preparation of the anhydrous chloride, and also of a new hydrate.—Study of the alloys of aluminium and molybdenum, by M. Leon Guillet. The reduction of molybdic acid by aluminium gives rise to no less than six compounds corresponding to the formulæ Al_7Mo, Al_3Mo, Al_2Mo, AlMo, $AlMo_4$, and a compound very rich in molybdenum, perhaps $AlMo_{20}$.—The crystallisation of cerium oxide, by M. Jean Sterba. The crystallisation of cerium oxide can be effected from sodium chloride, borax and potassium sulphate. It forms cubes or octahedra which are colourless and transparent.—Contribution to the study of cæsium, by M. C. Chabrié. A description of the sulphites and hyposulphites of cerium.—On the pyrogallol sulphonic acids, by M. Marcel Delage.—The action of ethyl alcohol upon barium ethylate. The synthesis of normal butyl alcohol, by M. Marcel Guerbet. By heating a strong solution of barium ethylate in ethyl alcohol in a sealed tube at 240° C., a small quantity of normal butyl alcohol is produced along with ethylene and hydrogen.—On the composition of the albumen of the seed of *Phoenix canariensis* and on the chemical phenomena which accompany the germination of this seed, by MM. É. Bourquelot and H. Herissey.—On the histological constitution of the retina in congenital absence of the brain, by MM. N. Vaschide and Cl. Vurpas.—Cultures and attenuated forms of the cryptogamic diseases of plants, by M. Julien Ray.—On the affinity of the red corpuscles of the blood for acids and alkalis and on the variations of resistance which they impress upon these reagents towards solanine, by M. E. Hédon.—On the nitrogenous nutrition of yeast, by M. Pierre Thomas.—The influence of lecithin upon the nutritive exchanges, by M. G. Carriere.

MIALL AND FOWLER'S "SELBORNE."

The Natural History and Antiquities of Selborne. By Gilbert White. Edited, with an Introduction and Notes, by L. C. Miall, F.R.S., and W. Warde Fowler, M.A. Pp. xl + 386. (London: Methuen, 1901.) Price 6*s.*

ECCE ITERUM! It is little over six months since the "painful" Mr. Sherborn compiled a bibliography of Gilbert White's matchless work, enumerating some 115 editions or issues of it, and here in England at least three more have since made their appearance, while we hear of another in America—to say nothing of the "Life and Letters" of the author now first fully given to light and recently reviewed in these columns (NATURE, July 18, 1901, p. 276)! Still, the edition of the evergreen classic, "Natural History and Antiquities of Selborne," with introduction and notes by Prof. Miall and Mr. Warde Fowler, deserves consideration here, for though these gentlemen have judiciously availed themselves of the labours of some of their predecessors in the art editorial and commentarial, they have added a good many notes of their own, not a few possessing a quite original character, while their introduction is of itself well worth reading.

Messrs. Miall and Fowler were, of course, too early to profit by Mr. Holt-White's biography of his great-grand-uncle, for their publication followed his by only a few weeks, and they must regret that this is so, since they depended for the most part on the statements of the late Prof. Bell, and naturally fell into his mistakes. From some of the worst of them, it is true, they might have saved themselves had they studied, instead of being content to mention, the memoir of Gilbert White which appeared more than eighteen months ago in the "Dictionary of National Biography"; but they seem, like most persons, to have supposed that an article in a dictionary is only for reference and not for reading. It may be said that, except in one case, their errors are of comparatively slight importance; but they have perpetuated the modern Oxford slander—now proved to be founded on imperfect acquaintance with the facts—that White was unpopular in his college and only held his fellowship there by holding his tongue, the sole ground of this imputation being two or three private memorandums of the then Provost of Oriel, who was temporarily smarting from a contested election in which White had been his rival. The two men had previously been friends, and it is satisfactory to know that friends they became again when the acrimony engendered by the competition had passed off. The worst of this mud having been thrown is that some of it will stick; but it behoves every member of that distinguished college—nay, every Oxford man—to do his best to wipe away this unfounded aspersion on White's fair fame. Mr. Fowler himself, we doubt not, must feel sorry that he has helped to spread this baseless accusation.

But our business here is not with White's book or life or character more than as they are dealt with by his present editors. With much of what Prof. Miall says we cordially agree, but when he writes that "White was a man of few books and of no great range of thought" we wholly dissent. It may be that he could not read French—easily at least—few Oxford clerics of his day could; but he certainly did know what Buffon was about, and Hérissant also, for he criticises both; and if he did not name Leeuwenhoek (who wrote in English, by the way) or Malpighi, why, we may ask, should he do so? Undoubtedly John Hunter was then dissecting, but for the most part of his life he was known to few as being more than a skilful surgeon, and what was there in the six or eight papers he had then published to call for White's notice of them? Prof. Miall remarks that "all the books which were essential to the 'Natural History of Selborne' would have gone into a single shelf." That is a mistake: the book of Nature is not to be shelved, and therein lay White's chief study. Again, we are told that he cared little for the British Museum or the Botanic Garden at Kew, and that Cook's voyages are not dwelt upon repeatedly and with interest. With all deference to Prof. Miall, such objections are futile. The collections then at the British Museum must have been extremely unimportant—the Museum of the time was the Leverian, which is repeatedly mentioned by White, and Kew Garden was the King's private affair, to which the public scarcely had access; but in Cook's voyages White plainly took very great interest, partly, no doubt, through his acquaintance with Banks, Cook's shipmate on the first of them. Reference to them is often made in his correspondence, though there was no need to bring it into his book. Surely Prof. Miall would justly resent being accused of indifference to the *Challenger's* voyage because we see no mention of it in the volume before us? We may charge him, however, with not having divested himself of the commonplace desire to fall foul of Pennant, who, he says, "was not enough of a zoologist to write books on zoology." This is amazing, for who then, we may ask, wrote the "British Zoology" (of which there were three editions and four issues in his lifetime), the "Indian Zoology" (two editions and a German translation), the "Arctic Zoology" (the same), to say nothing of the "History of Quadrupeds" and other works? It may be urged that in these labours he had assistance, and that some classes of animals met with scant treatment; but when has such not been the case? and in what other country were contemporary zoologies of similar character published with the same wealth of illustration? Prof. Miall admits that he was the best-known English zoologist of his day, and if in the later issues of the "British Zoology" his acknowledgment of White's aid was general rather than particular, is not the fact directly due to the latter having corrected, as he himself says he did, the former's proofs, when he naturally did not insert passages in his own favour? Unless Pennant in his own "Life" is guilty of positive misstatement, which there is not the least reason to believe, he expended very considerable sums in the illustration of his several works, and when he paid for the plates he reasonably thought he had some right to use them. This, we take it, was the cause of the misunderstanding, for it seems to have been nothing more, between him and John White in regard to illustrations for the latter's "Fauna Calpensis," which, unfortunately, was never published. It was natural for Gilbert White at first to take his brother's side and grumble at Pennant; but it would seem almost certain that explanations must have followed, and with them the discontent ceased. To us Pennant's influence on Gilbert White appears to have been distinctly advantageous, just as that of Barrington was the converse. No one can study Pennant's works without seeing that he was full of great ideas—whether they were original or not does not signify for our present purpose—and they were in the main true,[1] whereas Barrington's views seem to be always based on some prejudice or foregone conclusion, to support which he brought his very considerable forensic power to bear, and in the majority of cases arrived at an erroneous conclusion—take his ingenious argument as to the origin of the turkey, for example—and, though undoubtedly in many respects a benefactor, he was apparently White's evil genius in continually urging his absurd belief in the torpidity of the swallow-kind.

This remark brings us to Mr. Fowler's part of the introduction, in which he tries to account for White's astonishing adhesion to that belief, and his readiness to grasp at any scrap of information which seemed to support it, in spite of his own failure to discover a particle of evidence in its favour, and the fact that he fully accepted migration in the "short-winged birds" while doubting it in those that possessed far superior power of flight. Mr. Fowler's mode of accounting for White's "loyalty to an old delusion" seems hardly adequate, yet we must confess our inability to offer a suggestion that satisfies ourselves. We can hardly think that Aristotle, great as we admit was his authority in the Middle Ages, was responsible for the misconception, or even Olaus Magnus—much less Carew. They only repeated the stories of the vulgar and unreflective, and how Willughby's language on the subject "served to perpetuate the tradition" (as Mr. Fowler maintains it did) is more than we can understand. The whole thing is inexplicable, and is really the one flaw in White's reputation as a reasoning naturalist. Though in his earliest letter to Pennant (printed as No. x.) he frankly says that no account of swallows being found torpid in Hampshire is worth attention, the two instances he immediately cites—on the authority of "a clergyman of an inquisitive turn" and of "another intelligent person," each of them being in his boyhood—must have greatly influenced him. He can hardly be said to have been credulous on the subject. He simply thought that the evidence in favour of torpidity, though not satisfying, was such as ought to be tested, and he would no doubt have been pleased to obtain confirmation of it. In this respect he was like many people in our own day who engage in psychical research. Spirits refuse to come at their call from the vasty deep or boundless space, and search as he might, and did, amid the shrubs of Selborne Hanger or under the roofs of his neighbours' cottages, nor swift nor swallow would show itself.

Taken as a whole, the notes to this edition are very good, and those by Prof. Miall on the geology of the district are most acceptable, for few, if any, of White's recent editors have touched upon that subject. Those by Mr. Fowler on ornithology are for the most part extremely effective, whether culled from his predecessors or added from his own experience, and though he does suggest (p. 35) that the bird "so desultory" in its flight, at which White shot in vain, was a siskin and not a chiff-chaff, and (p. 83) would seem to consider the motion of the redstart's tail open to doubt, we have no such impossible suppositions as are found elsewhere to the effect that White did not know a crow from a rook, or the song of the wryneck from the cry of the pied woodpecker. If the introduction could be but freed from the blemishes we have here noticed, and a few more beside, this edition of the "Natural History and Antiquities of Selborne" might be recommended as one of the most accurate, as it is one of the neatest and most handy.

[1] The often-quoted case of the herring migration must, of course, be excepted, but therein he was misled by the reports of fishermen whom he trusted.

THE ORIGIN OF EUROPEAN PEOPLES.

The Mediterranean Race: a Study of the Origin of European Peoples. By G. Sergi. Pp 320; 93 illustrations in the text. The Contemporary Science Series. (London: Walter Scott, 1901.) Price 6*s.*

THE problem of our origins must always prove an interesting subject for research; speculation has found it only too fertile a prey. At the present state of our knowledge fresh information is being amassed continually, so that the field for speculation is, fortunately, becoming more narrowed. A recent contribution to the problem is from the enthusiastic Italian anthropologist, Prof. G. Sergi, of Rome, who has published in English an entirely new book, based on his "Origine e diffusione della stirpe Mediterranea," 1895. Those who are acquainted with the previous writings of Prof. Sergi will quite know what to expect in this new volume. The familiar arguments and data are reinforced by additional facts, and the author's conclusions are clearly and definitely stated. The following is the position he has adopted in this book, and which we may take as the expression of his matured views.

Homo Neanderthalensis is a distinct European species, which includes the Spy type and which originated in Europe in early Quaternary or possibly late Tertiary times. Hitherto it has not been found south of the Alps, and it has not completely disappeared from Europe, but persists in the Baltic, in Friesland and elsewhere.

The Chancelade, Laugerie-Basse, Baumes-Chaudes, Cro-Magnon crania constitute a group that extended from the Upper Quaternary into early Neolithic times. The view of Hervé and other French anthropologists is that this was a hyperborean stock that migrated from north to south as far as Africa, but excluding Egypt and the Canary Islands. Sergi shows that all the characteristics of the Chancelade skull are found in typical Mediterranean crania; indeed, he defines it as

"a *Pelasgicus stegoides* of the *Ellipsoides* class, still found to-day in East Africa. Why refer to the Eskimo, a skull to be found so near as the Mediterranean?" (p. 195).

The other cranial types are admittedly quite Mediterranean in character. If Scandinavia was not inhabited before the Neolithic period and northern Europe could not be inhabited by man until after the Glacial epoch, it is not easy to see how the centre and south of Europe could be invaded by a race originating in the north in the Quaternary epoch (p. 199).

The Neolithic dolichocephals, according to Sergi, were a northern migration of a group of *Homo Eurafricana*. This species may be divided into three races :—

"The *African*, with red-brown and black pigmentation ; the *Mediterranean*, of brunet complexion ; a *Nordic* race, of blond skin and hair, blue or grey eyes" (p. 259).

The Hamitic race never invaded Europe. In the late Quaternary epoch immigrations of the Eurafrican species took place from Africa into Europe. On the mainland of northern Europe a distinct differentiation took place so far as stature and pigmentation were concerned, but the cranial and facial forms were practically unaltered, and the Reihengräber type of the Germans and the Viking type of the Scandinavians were evolved. On pp. 252–255 the author discusses the obvious objections to this view. The whole of the Mediterranean basin, western Europe and the British Islands were inhabited by the brunet race.

The problem of the African blonds is fully discussed (pp. 59–83) by Prof. Sergi. After stating the views of various investigators, he says,

"It seems to me impossible to find in the blonds of Africa a racial element from northern Europe. If they had come at so early a period (in the times recorded by the Egyptian monuments) they would have radically modified Libyan civilisation beginning with funeral customs and imposed their own language" (p. 72).

In their "Libyan Notes" (1901), Messrs. D. Randall-Maciver and A. Wilkin state that the Berbers of Algeria are always a white-skinned people, and about ten per cent. are blond or fair-haired. Sergi is satisfied that the differences in colour of hair, skin and eyes between the darker and the lighter people are due to the influence of altitude, as the Atlas chain is the headquarters of the blonds in Morocco, and he regards these mountains as the centre of formation of the blond element in North Africa.

Neither of the European races of the Eurafrican species has anything in common with the so-called Aryan races. Sergi holds that it is an error to maintain that the Germans and the Scandinavians, blond dolichocephals, are Aryans. The Aryans are of Asiatic origin, and constitute a variety of the Eurasiatic species.

The anthropological unity of Europe, existing from the late Quaternary epoch and greatly increased during Neolithic times, was broken, at first peacefully and to but a slight extent, and afterwards violently, by a new species coming from Asia. Even in Neolithic times the advance guard of the wave of migration of the brachycephalic *Homo Eurasica* had penetrated slowly and peacefully into France. But then they began to come in larger and hence more turbulent bodies, and caused many changes. These invaders were savages inferior to the Neolithic Europeans, whose civilisation they in large part destroyed, replunging Europe into barbarism, also introducing the new burial custom of cremation, together with other customs, and transforming the existing languages into their own, which was a flexional language. To-day this new anthropological family, which also constitutes a zoological unit, bears three chief names, indicating three characteristic linguistic groups—Celts, Germans, Slavs. The skull of this species shows four primary forms—cuboid, cuneiform or sphenoid, spheroid and platycephalic—all corresponding to broad, brachycephalic skulls which contrast with the pentagonal, ellipsoidal, ovoid and arrow-shaped (beloides) cranial varieties of the Eurafrican species.

Wherever the Mediterranean stock established itself it preserved its primitive burial custom of inhumation and the characteristic architecture of the chambered tomb. This varies from the natural and artificial grottoes of the Mediterranean region to nurags, pyramids, dolmens and tumuli. Sergi has previously expressed the opinion that the prehistoric artists of the French caves, who possessed such developed artistic feeling, were the precursors of the historical artists who created the marvellous works of Egypt, Greece and Rome ; but he strongly holds the view that the Mycenæan or Ægean civilisation was largely of Asiatic origin, although he does not subscribe to the theory of Montelius that "the Mycenæan civilisation in Greece is due, not to an influence from another country, but to immigration of a new people." Sergi believes that the Asiatic immigrants, Pelasgo-Tyrrhenians and possibly others, were not anthropologically foreign to the Mediterranean stock. These, and the inhabitants of the Ægean Islands and the Peloponnesus, already possessed a pre-Mycenæan civilisation in common with the Afro-Mediterranean civilisation, but the new culture was the result of Asiatic influences, probably Mesopotamian and Hittite.

The introduction of bronze into Europe has been a fruitful subject for discussion. Sergi has given up the Celtic theory, and now believes that the importation of bronze was due to the Mediterraneo-Oriental culture.

The use of a script is so ancient that it had already reached definite shape in the Magdalenian epoch, that is to say earlier than the Neolithic times, as is proved by the painted pebbles in the cave of Mas d'Azil in the south of France ; and writing signs were widely diffused in countries peopled by the Mediterranean race in very ancient times. The languages of these peoples were also of Eurafrican origin, corresponding to the languages otherwise called Hamitic.

It is evident that this book bristles with debatable points, and we may look forward to interesting discussions from all quarters, as the intrepid Italian savant does not belong to any one school of Continental thought. Doubtless Prof. Ridgeway, for one, will have something to say to Prof. Sergi when the second volume of his "Early Age of Greece" is published. A. C. H.

A MECHANISM FOR THE TRANSMISSION OF STIMULI IN PLANTS.

Die Reizleitung und die reizleitenden Strukturen bei den Pflanzen. Von Dr. B. Nemec. Mit 3 tafeln und 10 abbild. im Text. Pp. 153. (Jena : Verlag von Gustav Fischer, 1901.) Price Mk. 7.

IT has long been known that certain parts of many plants are capable of being irritated by appropriate means, and that the stimulus thus perceived is in some way transmitted through an intervening quiescent region to a spot or zone at which it is translated into a definite motile reaction. But it has also been constantly denied that there exists in plants anything comparable to the nervous system of animals; and the transmission of the stimulus has commonly been referred either to a serially altered condition of the protoplasm in its relation to water, or to vague suggestions arising from the well-known facts of protoplasmic continuity between adjacent cells, the onus of transmission being cast on the protoplasm as a whole.

Dr. Němec, however, contends that these notions demand reconsideration, and he gives an account in the book before us of observations which, if confirmed by subsequent examination, are of great importance as enabling us to obtain a more definite comprehension of the relations existing between perception and reaction in the motile organs of plants.

The author begins by studying the effects on the protoplasm of wounding the sensitive regions of roots and other organs, and, in the main, he confirms, and at the same time extends, the conclusions arrived at by Tangl some years ago. He distinguishes two traumatic phases as consequent on such an operation. The first, or *primary*, response consists in an aggregation of the protoplasm, and it may be of the nucleus also, to the wound-ward end of the cell. This effect is propagated with diminishing rapidity in a direction away from the wound, and at a rate which is not equal for the different tissues composing the organ. A curious fact relating to the travelling onward of the effect is brought to light in connection with cells in which nuclear division is proceeding, for the disturbance appears to miss these cells, though it reappears immediately beyond them. Shortly after this primary manifestation has passed over a cell, recovery supervenes, only, however, to give place to a *secondary* phenomenon. The protoplasm of the cells in the vicinity of the wound assumes a more or less gelatinous character, and the vacuoles begin to undergo fusion. This secondary effect is, however, apparently rather local, and travels neither so far nor so fast as does the primary one. It may perhaps be questioned whether the latter is not, at least mainly, due to a disturbance of hydrostatic equilibrium in the cells consequent on the lesion of the organ, whilst the secondary change may possibly be associated with the febrile condition known to be induced by mechanical and other injuries. Further investigation of the phenomena by means, *e.g.*, of plasmolysing reagents might prove of interest.

Of more general importance than these results is the statement that the author has succeeded, by means of appropriate stains, in demonstrating a continuous fibrillar structure in the cytoplasm. These fibrillæ, which are figured as somewhat thick cords, traverse the cell chiefly in the longitudinal direction; and, although the point was not definitely settled, they appeared to connect with similar ones in the contiguous cells of a longitudinal series. They are not equally present in every kind of tissue, sometimes they occur in the cortex whilst in other cases they are most abundant in the plerome. They are almost always met with in sensitive and motile organs, to which also they appear to be almost exclusively confined, and Němec believes that they represent the means whereby stimuli are rendered transmissible. He finds that conditions which impair or abolish such transmission also affect the fibrillar structure. The latter may, indeed, be temporarily or permanently disorganised, and so long as this is the case the organ appears to be insensitive.

Němec himself considers some of the objections which may be urged against his view of the functions of the fibrils. Thus it might be argued that the same causes which result in a dislocation of the sensitive mechanism of an organ may also, and concomitantly, destroy the normal structural configuration of the protoplasm, but that it does not therefore follow that the two should necessarily stand in any causal connection with each other. The force of such an objection is, however, weakened by two observations made on roots. In *Vicia*, the fibrils are restricted to the axile cylinder (plerome) of the root. Now if the cortex be severed by an annular cut, after the disturbance which ensues as the result of the injury has passed away, the organ recovers the power of perceiving and transmitting stimuli; if, however, the plerome be cut through, by means of a needle, then the power of future response in the case of stimuli affecting the distal end will be found to have been finally lost. Again, it is known that the perception, by roots, of the stimulus given by gravity is limited to the actual growing point, whilst the motile region, in which the stimulus provokes a visible result, is situated at some distance behind it. If the tip of the root be cut away, the power of further response to the gravity-stimulus is thenceforth in abeyance pending the regeneration of the apex. Now in some instances it was observed that the power of response to the stimulus was not recovered even after the formation of the new growing point, but in every one of these cases further examination showed that the fibrillar continuity had not been properly restored. Hence the path of transmission between the percipient apex and the executive motile portion of the root still remained interrupted.

It is clear that Dr. Němec has opened up a promising field of investigation, and one which is no less important from the point of view of the plant world than from that of the lower animal organisms in which also no permanent nervous system is present. It is to be hoped that the observations may be thoroughly tested by physiological as well as by histological methods, a task which should be rendered the easier inasmuch as the structures can apparently be identified in the still living cells.

J. B. F.

AMERICAN AGRICULTURAL RESEARCHES.

Yearbook of the United States Department of Agriculture, 1900. Pp. 888. (Washington, D.C., 1901.)

THE bulky volume before us is as full of interest as its predecessors, and as profusely illustrated. Its contents are extremely various, for, as mentioned in the preface, there is not a single bureau, division or office of the Department that has not contributed to the present book. The reports occupy 633 pages. These are followed by an appendix of 231 pages, in which a great deal of statistical and miscellaneous information is brought together for the use of the farming community. We can only refer to a very few of the subjects discussed.

The report on the cultivation of Smyrna figs in California is full of interest of many kinds. For this fig to be brought to perfection, it is necessary that the flower should be fertilised by pollen from the wild fig, or caprifig. The pollen is conveyed by an insect, *Blastophaga grossorum*, which goes through its various stages of growth in the wild fig. It is the practice in Smyrna and other fig-growing countries to break off the fruits of the caprifig, and tie them to the limbs of the edible fig tree, at the time when the flower receptacles of the latter are in a suitable condition. The result is the production of figs far larger and finer than would be obtained without this operation. The American report gives a brief history of our knowledge on this subject, and a detailed account of the introduction of the Smyrna fig into California, the subsequent introduction of the caprifig, and the final successful introduction, after several failures of the insect, with details of the work done during the season of 1899, when the first crop of figs fully equal to the imported article was obtained. For the successful fertilisation of the Smyrna fig it is necessary that the caprifig should blossom at the same time as the Smyrna fig, and that the winged female insect should also at the same time be emerging from the galls containing the pupa. These adjustments are liable to be disturbed by variations in climate and season, and require careful study and skilled scientific superintendence if fig culture is to be successfully introduced into a new country.

The report on the cultivation of the date palm is also of great interest. A full account is given of the conditions under which the finest dates are produced in Algeria and the Sahara, and of the steps which have been taken to introduce the best varieties of the date palm into Arizona and other suitable climates in the United States. It is shown that the best varieties can only be introduced by means of offshoots, the plants grown from seed being very various in character. Different climates require the choice of different varieties. The tree has the great merit of flourishing in climates in which the summer is too hot and too dry to permit of ordinary cultivation; it flourishes even in soils impregnated with alkali salts, a condition frequently met with in dry climates. The report should be of considerable value to the Agricultural Department of our Indian Empire, where vast areas of waste alkali land are still waiting to be dealt with.

There is one more report, of special interest in connection with the present summer, of which we will briefly speak: its subject is hot waves, the conditions which produce them and their effect on agriculture. The continent of North America is at present admirably suited for the study of meteorological phenomena; the observers cover an immense area, and are all in telegraphic communication with the Central Weather Bureau at Washington. The report in question includes the study of three remarkable periods of heat, and is illustrated by maps showing the distribution of pressure and temperature over the continent during these periods. The first point that strikes one is the unsuitableness of the phrase "hot wave." The heat periods are, indeed, periods of stagnation in the atmosphere. The conditions appear to be similar in each instance which is discussed. There is an area of moderately high pressure in the subtropical region towards the south-east; an area of moderately low pressure in the northern central States, and a second area of high pressure on the west or north-west coast. These conditions are steadily maintained during the hot period. There is, of course, a slow flow of air from the subtropical, south-eastern area of high pressure to the central or north-central area of low pressure. The extreme temperatures occur between these two regions. The great heat is not simply due to air coming from a warm region; it is largely due to the clear sky affording full opportunity for the receipt of solar energy, and to the small radiation during the night from the earth's surface; the hot nights are, indeed, a striking feature of these periods. What is the cause of this absence of night radiation with an apparently clear sky? It appears to be due to the presence of a large quantity of transparent water vapour in the higher regions of the atmosphere, which allows the passage of solar radiation but forbids the return of the lower grade heat waves of terrestrial radiation.

R. WARINGTON.

SCHOOL HYGIENE.

School Hygiene. By Edward Shaw, Professor of the Institutes of Pedagogy, New York University. Pp. 260. (London: Macmillan and Co., Ltd., 1901.) 4*s.* 6*d.* net.

A Manual of School Hygiene. By E. W. Hope, M.D., Professor of Hygiene, University College, Liverpool, and E. A. Browne, F.R.C.S.E., Lecturer of Ophthalmology, University College, Liverpool. Pp. 207. (Cambridge: University Press, 1901.) 3*s.* 6*d.* net.

IT has been the aim of the authors of these two works to set forth the conditions which should surround school pupils in order that their mental and physical health may be promoted. No true education in mental training can overlook the hygienic and physical relationship of mind and body, and no knowledge must be conveyed at the expense of physical and moral development; for it is true, as Mr. Herbert Spencer has reminded us, that the essential object of education is to teach us how to live happily. Moreover, the connection between physical health and the power of voluntary control and, consequently, of conduct, is very close, and perfect mental development cannot be brought about if the opportunity is not given for healthy physical development. Notwithstanding the general acceptance of these truisms, school buildings are still being erected with a view mainly to exterior effect, and an adequate system of ventilation in the crowded class-rooms is rarely to be met with. As Prof. Shaw has pointed out, the school-room should be the unit first to be considered in planning the school building, and the building should be a number of school-rooms properly disposed, and not a whole cut up into school-rooms whose size and arrangement are dependent upon the size and shape of the building.

The guiding principles of hygiene, so far as it is affected by the circumstances of school life, are well and clearly set forth in both books, and the essential facts of school health are brought within the easy reach of the parent or teacher. To do their duty in this respect, no great amount of detail knowledge is necessary, but rather one of general principles combined with an intelligent observation of children with the view of detecting those influences which tend to do harm. Many details in the practical work of the school are of the greatest hygienic importance, and these can only be directed by the teacher, who should recognise that it is the first duty of an educational system to promote good health among the scholars, and, indeed, that the success of any particular school is reflected in the physical health of those attending it as well as in their mental attainments.

"A Manual of School Hygiene" consists of two parts. In Part i., written by Prof. E. W. Hope, there are chapters upon site and soil, the school building, air, ventilation and warming, food and clothing, sickness, the personal aspect of infection, accidents and emergencies. Part ii. is written by Mr. E. A. Browne, and deals with the care of the eye, school furniture and writing, the air passages, exercise, over-pressure and the general management of health. The subjects of Part i. are not always treated with sufficient detail to meet the purposes of an elementary text-book. For instance, it is not sufficient to state that "other simple inlets for fresh air may be mentioned, such as Tobin's tubes, Louvres, Sherringham valves, Cooper's discs, &c." (p. 33); and again, that house drains "should be laid at such an inclination as will secure a velocity of not less than three feet per second, and the diameter should be four or six inches in accordance with the number of lavatories discharging into it" (p. 10). Many other instances could be quoted in which the matter given will convey little real information to one who already knows little or nothing of the subject. Owing to a hasty revision of the proof sheets, the carbonic acid of the general atmosphere is given as 0·4 per cent. on p. 16.

The treatment of the subjects of Part ii. is wholly excellent; the matter is scientifically sound, clearly written and sufficient, and it might well serve as a model to other text-books which deal with corresponding branches of school hygiene. We would commend Mr. Browne's definition of "over-pressure" as a very happy one; it is "a failure to reach the potentiality of the bodily and mental strength of any given child"; and every school teacher would do well to keep before him the writer's statement that "the holidays may be needed for the teachers, they may be desirable for the maintenance of home life and family ties, but they should be entirely superfluous in the matter of health."

The long range of subject-matter comprised within the title, "School Hygiene," is also dealt with a little unevenly in Prof. Shaw's work. The book contains some excellent chapters, notably those dealing with school furniture, postures, physical exercises and handwriting; but those dealing with sites and foundations of schools and sanitary fitments are somewhat poor, and generally insufficient. The reader will be puzzled by the reference, in the chapter dealing with ventilation, to "the well-known device of placing a board between the sashes of the window," and the scientific reader will not approve of the statement that the soil of the site should be free from organic matter. The book, however, is one which contains a great deal of valuable and well-expressed material, and it should be read by all those whose duty it is to be conversant with the subject of school hygiene. It is well printed, excellently illustrated, and contains a good bibliographical appendix.

OUR BOOK SHELF.

Illustrations of the Botany of Captain Cook's Voyage Round the World in H.M.S. "Endeavour" in 1768–1771. By the Right Hon. Sir Joseph Banks and Dr. Daniel Solander, with Determinations by James Britten, F.L.S., Senior Assistant, Department of Botany, British Museum. Part II.: Australian Plants. (London: Printed by order of the Trustees of the British Museum, 1901.)

THE first part of this work was noticed in NATURE, lxii. p. 547, October 1900, to which we may refer for explanations of its scope and character, as well as for some criticisms of the nomenclature and other points. The present part consists of plates 101 to 243, with descriptive letterpress, and illustrates the natural orders Myrtaceæ to Labiatæ, arranged after Bentham and Hooker's "Genera Plantarum." When complete, this work will be a great help to the botanists of East Australia, as it will comprise a considerable selection of the plants of the coast region from Cape Howe to Cape York. Almost all the natural orders are represented, though somewhat unequally. Thirteen genera of Myrtaceæ are figured, for example, and they include eight which are characteristically Australian. Nine species of the delicate and elegant genus *Utricularia* are also among those represented. In the way of names, such familiar genera as *Barringtonia*, *Careya*, *Sesuvium*, *Spermacoce*, *Olearia*, *Wahlenbergia*, *Trichodesma*, *Clerodendron* and *Plectranthus* are superseded by the obscure and usually less euphonious appellations of *Huttum*, *Cumbia*, *Halimum*, *Tardavel*, *Shawia*, *Cervicina*, *Borraginoides*, *Siphonanthus* and *Germanea*, respectively, on the ground of priority, often for a single species. Fortunately for the ordinary botanist and gardener, these and numerous other changes are not binding, and most of them are not recognised by Kew, Berlin and other botanical establishments which greatly influence the horticultural world. But the saviours of the familiar names are the nurserymen, who are careful not to mislead and mystify their customers by using fresh names for old plants.

W. BOTTING HEMSLEY.

Essays on the Theory of Numbers. I. Continuity and Irrational Numbers. II. The Nature and Meaning of Numbers. By Richard Dedekind. Authorised translation by W. W. Beman. Pp. 116. (Chicago: The Open Court Publishing Co.; London: Kegan Paul and Co., Ltd., 1901).

IN the first of these tracts Prof. Dedekind gives a theory of irrational numbers and of the arithmetical *continuum* which is logically perfect, and in form, perhaps, more simple and direct than any other which has been or could be suggested; in the second he proceeds, by a marvellous chain of subtle inferences, from the idea of a *manifold* (or system of distinguishable objects in the widest sense) to the series of natural numbers and the elementary operations of arithmetic. It is to be hoped that the translation will make the essays better known to English mathematicians; they are of the very first importance, and rank with the work of Weierstrass, Kronecker and Cantor in the same field. The translation is rather painfully literal, and does not convey much idea of the graceful style of the original; but it is, on the whole, correct. On p. 46, l. 15, "hereafter" is a wrong rendering of *hierauf*; on p. 52, l. 18, $\psi(s')$ and s should be $\psi(S')$ and S; p. 61, last line but one, "such" is superfluous. On p. 34 there is an amusing complication of errors. What the author means is, "In this sense" (or "in the light of this fact"), "which I wish to express by the words ἀεὶ ὁ ἄνθρωπος ἀριθμητίζει, formed after a well-known saying, I hope," &c. The reference is to the motto on the title-page of the German edition, which was coined by the author in imitation of the Platonic dictum, ἀεὶ ὁ θεὸς γεωμετρίζει.

M.

Familiar Butterflies and Moths. By W. F. Kirby, F.L.S., F.E.S. Pp. 114; with 18 plates containing 216 illustrations in colour. (London, &c.: Cassell and Co., Ltd.) Price 6*s.*

THE interest of this book centres in the coloured plates, which for the most part are excellent, and, so far as they go, will enable any one to name his insects supposing them to be among the number figured, for it must be remembered these are only a "selection." Probably the only really bad figure is Fig. 11 on Plate x. Nearly one-fourth of the number are butterflies, and nothing is figured beyond the Geometridæ. A not inconsiderable number of the species noticed do not occur in Britain, but this should be no drawback, because so many of our amateur entomologists travel abroad nowadays and form collections on their tours. The text is written to the figures and is sound, and the whole book is remarkably well got up. It does not pretend to be of the strictly scientific class, but we can commend it to the notice of those desirous of making a cheap, handsome and useful present.

Lehrbuch der mathematischen Chemie. Von J. J. van Laar. Pp. xiii + 224. (Leipzig: Johann Ambrosius Barth, 1901.)

THIS book does not cover the whole ground of mathematical chemistry, but is concerned solely with equilibrium. The treatment is thermodynamical throughout, Planck's potential function being taken as mathematical basis.

The first section of the book gives the general thermodynamical theory; the second section, which has eight times the bulk of the first, applies the theory to concrete cases, examples being given of all ordinary equilibria in gaseous, dissolved and condensed systems.

To those who desire a formal mathematical treatment of this important branch of chemical theory the book may be heartily commended, more especially as due attention is paid to experimental work where possible, so that comparison between theory and experiment is made easy.

Philip's Educational Terrestrial Globe. Diameter 9 inches. (London: George Philip and Son, 1901.) Price 15*s.*

IT is unnecessary here to urge that familiarity with the features of a good terrestrial globe is an excellent faculty for the student of geography to possess. Good globes of a serviceable size should be regarded as essential to the satisfactory teaching of the subject. Messrs. Philip's new globe shows commercial routes, ocean currents and the new political boundaries; and it is a very clearly-printed representation of the world. The distances in nautical miles are shown upon the principal steamship routes. Of course it is impossible to represent details upon a globe nine inches in diameter, as the scale is so small that the British Isles can be covered with a threepenny piece. But the correct general view obtained by the inspection of even a small globe has many advantages in the early stages of geographical instruction. For real work, however, it is essential that a complete meridian divided into degrees, and a wooden horizon, be provided. The importance of this is apparently not sufficiently appreciated by globe makers, for all the comparatively cheap globes, such as that under notice, are mounted with a semi-meridian of brass, which is sometimes not even divided into degrees, and they have no horizon. It ought not to be difficult to devise a light and inexpensive globe having both meridian and horizon, and doubtless such a globe could be produced if geographical publishers cared to give attention to it. The great value of a globe of this kind in connection with problems of geodesy, navigation and physical geography can only be appreciated by those who have learnt or taught the use of the globes.

Die Krystallisation von Eiweissstoffen und ihre Bedeutung für die Eiweisschemie. By Dr. Fr. N. Schulz. Pp. 43. (Jena: Gustav Fischer, 1901.) Price M. 1.20.

THE investigation of the chemical and physical nature of albumins[1] has always been hampered by the absence of criteria for the determination of the purity of the specific preparation. In chemical research we possess in crystallisation our most valuable method for purifying a substance, but the application of this method to albumins presents a complex problem.

For albumin crystals—crystalloids as they are termed—possess remarkable properties which distinguish them from other crystals: when treated with various reagents they absorb liquid and swell up; they do not separate from pure solvents, but the crystallisation is effected by salting out, or by the addition of mineral acids; as soon as the crystallisation is started, the separation is spontaneous and independent of the concentration, rendering it impossible to grow large crystals.

In other respects, however, these crystalloids resemble true crystals, in so far as they belong to well-defined systems, possess similar optical properties, and their inclination towards crystallisation depends on their state of purity.

Dr. Schulz in this pamphlet gives a complete account of all albumins which occur or have been obtained artificially crystalline, and of the methods used to obtain the latter results, and indicates that in many cases the elementary analyses of crystalline albumins, by different experimenters, show a welcome agreement.

Though Dr. Schulz in no wise dogmatises on the two theories of the crystallisation of albumin, he inclines to the view put forward by Hofmeister, who considers the phenomenon simply a case of gradual purification, in preference to Gabriel's assumption of the depolymerisation of the molecules of amorphous albumin.

The object of the author, we think, is in the first place to demonstrate the comparative uselessness of scientific research on substances of the purity of which we have no guarantee; he does not believe the amorphous character of certain albumins to be an inherent property, but attributes it to our ignorance of experimental conditions, intensified by the sensibility and labile nature of the albumin molecule. We can warmly recommend Dr. Schulz's pamphlet to the physiological chemist.

W. T. L.

Flowers and Ferns in their Haunts. By M. O. Wright. Pp. xix + 358. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1901.) Price 10*s.* 6*d* net.

THE authoress, in the "invitation" which prefaces this book, asks her readers to "spare an idle hour to look with the eye of the mind and the camera at a few of the flowers and ferns in their haunts." From this it will be evident that the work is not in any sense a scientific one and must not be criticised as if it were. It is a pleasantly written account of the more familiar flowering plants and ferns met with in a district in North America as they present themselves in the landscape. It is very fully illustrated with plates and drawings, the former being reproduced from photographs, the latter based on them. The plates, which represent the plants as they grow, are very good. The book will interest those who are familiar with the plants of which it treats, while others who know the wild plants of England will obtain from it a general idea of the common wild flowers of another country. A useful feature is a list of the scientific names of plants, which are mentioned in the text by their local popular names.

W. H. L.

[1] English current literature writes album*e*n and album*i*n indifferently—in America the term "egg-white" is frequently used, but rarely album*e*n.

Pearl and Pearl-shell Fisheries.

IN connection with Sir West Ridgeway's anxiety, as Governor of Ceylon, to revive the pearl fishery off the north-west coast of the island, and the appointment by the Secretary of State for the Colonies of so able a zoologist as Prof. Herdman to report on the subject—so classic to zoologists since Dr. Kelaart's paper and the display of fine examples of the pearl shells by the Indian Government in the London Fisheries' Exhibition of 1883—it may be interesting to mention the activity of the Queensland Government in this and allied subjects. Besides the work of Mr. Saville Kent and the recent (private) investigations of Mr. Lyster Jameson, the Queensland Government early last year appointed an able young zoologist, Mr. James R. Tosh, to make investigations on the life-history of the species which produces the pearl-shells of commerce, the formation and growth of pearls, and other questions bearing on the pearl fishery. He is now busy on Thursday Island. Moreover, Mr. Tosh informs me that the Queensland Government has just sanctioned a grant of 1500*l*. for the erection of a marine laboratory on a small island about two miles distant (from Thursday Island), and in the centre of the pearl-fishing grounds, though at some distance from the coral area. This laboratory will have, besides the work-room and quarters for Mr. Tosh and his staff, three concrete tanks for experimental work. W. C. McINTOSH.

Barham, Springfield, Fife.

A Possible Method of Attaining the Absolute Zero of Temperature.

IN your issue of July 25 there appeared an interesting article on the liquefaction of gases. It was shown that by rapidly evaporating hydrogen, Prof. Dewar obtained a temperature of 13–15° C. (absolute). By a similar use of the more volatile helium, probably an even lower temperature could be obtained.

But, as the author pointed out, such methods will not enable us to reach the absolute zero itself.

May I be allowed to suggest that thermoelectric phenomena will be of some use in attaining the desired result?

Peltier showed that if a current be passed across an antimony-bismuth junction, in one direction heat is developed and in the reverse heat is absorbed and an appreciable cooling effect obtained.

Similarly, in the case of any two other metals, heat is generated if the current traverses the surface of contact in one direction and is consumed if it passes in the opposite direction—the quantity of reversible heat being in each case proportional to the strength of the current and to a coefficient π, depending on the nature of the metals and their temperature.

So that, in general, if r is the resistance of the part of the circuit containing the junction, the energy converted into frictional heat is C^2rt and the energy converted into reversible heat is $C\pi$.

Hence, if H be the quantity of heat produced in t seconds we have:—

$$J.H = C\pi t + C^2rt.$$

By making a small hole at the junction of a bismuth and antimony bar, in which was placed a drop of water and a small thermometer, the whole being cooled to zero, Lenz found that when a current was passed from bismuth to antimony the water was frozen and the thermometer sank to −3·5° C.

Opposing this fall in the junction's temperature there are, in general, two influences. Firstly, when a current is passed through a conductor a frictional generation of heat occurs, which tends to mask the cooling effect. Secondly, when one part of a circuit is at a much lower temperature than the other parts, heat will flow by conduction from the hotter to the colder parts and thus again oppose further cooling.

When a stationary low temperature has been reached by the junction, we must suppose that as much heat is absorbed by the current in unit time as is imparted to the junction by means of both of those influences I have mentioned working together.

If, therefore, we could diminish or do away with these, a very great cooling effect could be obtained.

The frictional heating effect could be eliminated to a great extent by cooling the whole to the lowest temperature attainable by the use of liquid hydrogen. Recent experiments by Profs. Fleming and Dewar show that an astonishing fall in the specific resistance of most metals takes place at very low temperatures. Thus the specific resistances of copper and iron fall from 1564 and 9115 respectively at 0° C. to 289 and 1220 at −200° C., while at a temperature only 20° C. lower, these numbers become 144 and 660—*i.e.* the specific resistance at −220° C. is actually half that at −200° C. (*vide* Foster and Atkinson's "Electricity and Magnetism," p. 162, 1896 ed.) Such an enormous diminution in the specific resistance leads one to expect that at only 13–14° C. from the absolute zero—the lowest temperature yet attained by Dewar—the resistance would be practically negligeable, so that the term C^2rt in the above expression would become extremely small even when currents are employed considerably more powerful than those which can be used at ordinary temperatures for producing the Peltier effect.

If, then, π remained appreciably large, it is quite possible that matter could by such means be chilled almost to the absolute zero without the masking effect of frictional heat becoming sensible.

The second influence, namely, the flow of heat by conduction from the hotter parts of the bar to the cold junction, could be eliminated by avoiding a sensible temperature difference between the chilled junction and the rest of the circuit. For instance, each small section of the main circuit could be cooled simultaneously with the junction by means of a number of other chilled thermoelectric junctions. By the use of some such contrivance, the temperature of the junction need never become very much lower than that of the rest of the circuit.

The coefficient π would certainly alter with the temperature; unless it completely vanishes for all bodies at very low temperatures, such an effect could be corrected by suitably choosing the metals forming the junctions. GEOFFREY MARTIN.

Bristol, July 26.

Food of the Senegal Galago.

THE following facts may interest some of your readers as pointing out the possibility of a rare tropical animal being able to maintain itself unaided for some weeks in an English country town.

On the evening of June 20 an African galago (*G. senegalensis*) escaped from my laboratory in Eton. For some little time it was not seen or heard, but after that it constantly made its appearance in gardens, on house roofs, &c., until, on the night of July 28, it was caught while rifling a cupboard. Previous to this date it had never been seen inside a house, so that how it managed to obtain food is somewhat of a mystery. Probably it lived on fledglings which it took out of the nest, and later on the decrease in their numbers forced it to forage for less tempting prey. Its strictly nocturnal habits and great agility no doubt preserved it from being destroyed by dogs. M. O. HILL.

Pseudoscopic Vision without a Pseudoscope.

THE curious optical illusion which has been noticed by Prof. R. W. Wood and described by him in NATURE for August 8 under the heading of "A New Optical Illusion" has been known for many years.

It is mentioned in Helmholtz's great work on physiological optics in the chapter on the stereoscope and pseudoscope. It appears to have been first described by Prof. Joseph Le Conte in 1869 (see Silliman's *American Journal of Science* for January 1869 and *Phil. Mag.* February 1869).

Both these authorities mention a further similar illusion not described by Prof. Wood, which I think is a more striking illusion. If one looks at a pattern of which the distance between the centres of contiguous figures is somewhat less than the distance between the two eyes, and if we gaze at it in such a manner as if we were looking at a distant object beyond it, we then get the illusion of a much increased pattern at a considerably greater distance from the eye. A. S. DAVIS.

Roundhay, Leeds, August 9.

PHOTOGRAPHIC ANALYSIS OF THE MOVEMENTS OF ATHLETES.[1]

M. MAREY has again applied his chronophotographic methods in making an analysis of the movements of athletes while exercising their strength in different ways. His delightful experiments, which have been but little repeated by others, are described in detail in "Le Mouvement" (par E. Marey. Paris: 1894. Translated into English by E. Pritchard. London: Heinemann,

FIG. 1.—Composite picture of putting the weight by Sheldon.

1895). The methods are, for the most part, so simple, and the results so valuable, that they should prove themselves attractive to the student of those subjects in which movement of any kind is to be measured. In 1900, during the exhibition in Paris, there was a large gymnastic meeting and athletic sports. The administration of the exhibition nominated a commission of physiology and hygiene, for the purpose of following the meetings and gathering from that unique assembly of the best athletes in the world the information which it afforded. Its object was to determine, from a physiological point of view, the action of the various forms of exertion on the organic functions, viz. the respiration, the circulation of the blood, the digestion and, finally, the general health. The commission also studied different kinds of sports with a view to understand their mechanical details and discover the secret of the superiority of certain athletes.

The chronophotographic method gives a series of instantaneous photographs, on a long ribbon which is unwound; the number of pictures varies from fifteen to twenty or more per second. By this means the phases of a movement are perfectly represented. Figures so produced on a band being somewhat difficult to compare with one another, it was found to be more convenient to arrange them, as in Fig. 3, in three columns, the succession of pictures in each column reading from top to bottom, commencing on the left. The subject is that of "putting the weight" by the American athlete, Sheldon. The weight used by all competitors was 7·25 kilogrammes, = 15·95 lb., or the 16 lb. shot used in English athletic sports, and the distance covered was 14·02m. = 45·98 feet. Fig. 3 shows the athlete at the moment of his take-off from the right leg. At the end of his jump, and at the moment when the left foot touches the ground, he brings his right arm into action, which moves the shot upwards and forwards, giving it the greatest velocity possible.

The competitor is allowed a run of 2m., and he stands in a square traced on the ground, the boundary of which he must not pass. In order that the velocity of the different movements of the athlete may be estimated, it is necessary to introduce into the pictures the representation of both time and space. The time is measured by means of a chronograph (visible only in the five last pictures); it consists of a black dial furnished with divisions, over which a white pointer moves; the pointer makes one revolution in one second. The angular space swept out by the needle between two successive pictures indicates the time which has elapsed. An easy way of measuring these intervals is to determine the number of images contained in one, a half or quarter revolution of the needle. In Fig. 3, the last five pictures were made in one quarter of a revolution of the pointer, or at the rate of twenty pictures per second, so that between two successive images the displacement (which is estimated for any point on the body) is made in 1/20th second, and it is the same for the displacement of the weight. The true extent of displacement is finally determined by placing a divided metric scale on the ground; this rule is photographed at the same instant as each new position of the athlete, and it serves as a scale whereby the path traced out by each point under consideration may be computed—M. Marey gives the following *method of comparing images by superposition.*

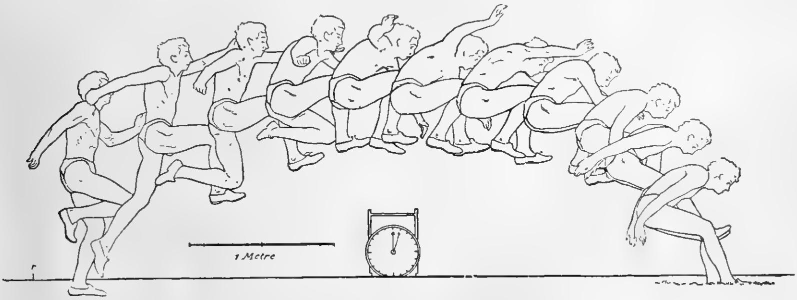

FIG. 2.—Composite picture of long jump by Sweeney.

[1] The accompanying illustrations are from *La Nature.*

Project the first image of a series (Fig. 1) on to a piece of paper, mark the ground line and a fixed point on it, r—a small stick planted in the ground—then trace with care the contour of the body and limbs of the gymnast. This done, project the second figure of the series. In order to bring this image into its correct position, relative to the first, shift the paper until the ground line and the point of reference correspond with those points already marked on the paper. We shall see that the second image does not coincide with the first; since each part of the body has moved, trace the outline of the second image and repeat the operation for each image in the series. The result is a composite diagram, and by reference to the original pictures it is easily interpreted. In the composite diagram only every third image in the original has been used, otherwise the result would have been confusing. In Figs. 1 and 3 the movements of the athlete are put before us in series. He begins with a jump, which imparts a certain acceleration to the shot; during this period the arm is inactive, since the shot rests on the shoulder. Next is added a new acceleration, due to the arm. In order to discover, for example, the force acting on the shot at any instant, all the images of the shot must be represented (the figure of the man being left out, as it would complicate the diagram). After the successive positions of the shot have been traced on the paper, the accelerations can be determined and their curve traced; by means of this the work done by the

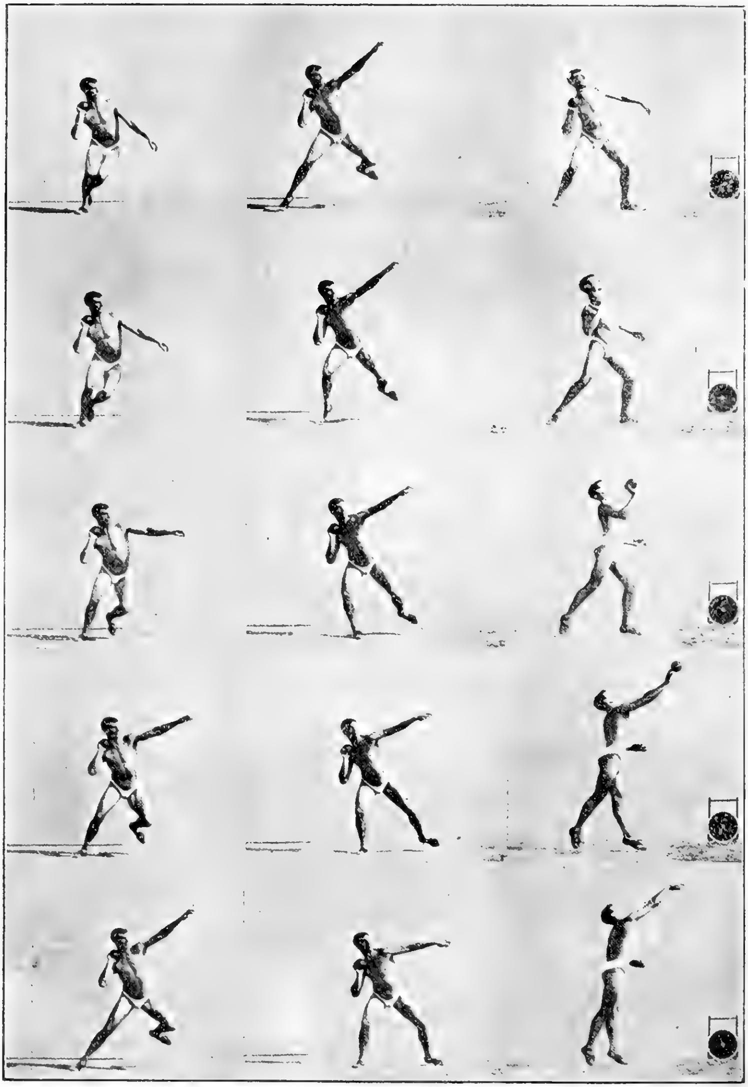

FIG. 3.—Putting the weight by Sheldon.

athlete at any instant may be found. M. Marey's excellent work in chronophotography is again illustrated by the analysis of the long jump (Fig. 4). The columns are to be read from right to left and from top to bottom. As in the former diagram, a composite picture has been made from several consecutive images. In this instance, owing to the rapid movements of the jumper, the figures have less tendency to be confused by superimposition. By eliminating every other image, a clear and comprehensive representation of all the actions has been obtained — actions which no language could describe with sufficient accuracy. The means of determining the extent and the duration of these movements is as perfect as possible. The chronograph shows that the interval between the images is 1/14th second, whilst the metric scale gives the length of the jump as 4·69 m. The same method of measurement shows that the space traversed by the jumper in 1/14th second was 52 cm., giving him a velocity of 7·28 m. per second. If the detail of Fig. 2 is closely studied, it will be seen that different points of the jumper's body do not cover the same space in the same time. For example, the head is displaced with unequal velocities, because the arms and legs are at each successive moment in different positions. Several other analyses of the movements of celebrated athletes, French and American, were obtained, and in all cases much light has been thrown on the rapid movements of the limbs in the case of clearing hurdles in a race.

The evidence collected in each section of the inquiry instituted by the commission of physiology and hygiene should prove itself to be most interesting and valuable matter, since it should lead to a complete modification of the system of athletic training and establish it on the study of nature itself, instead of on theories devoid of experimental foundation and often contradictory. M. Marey's methods of time measurement are very excellent, simple and effective, and a study of his work, "Le Mouvement," ought to stimulate English experimentalists to work in the same direction, which should prove itself to be a fruitful field for research in a country in which athletic exercises of every kind are so vigorously practised by all classes.

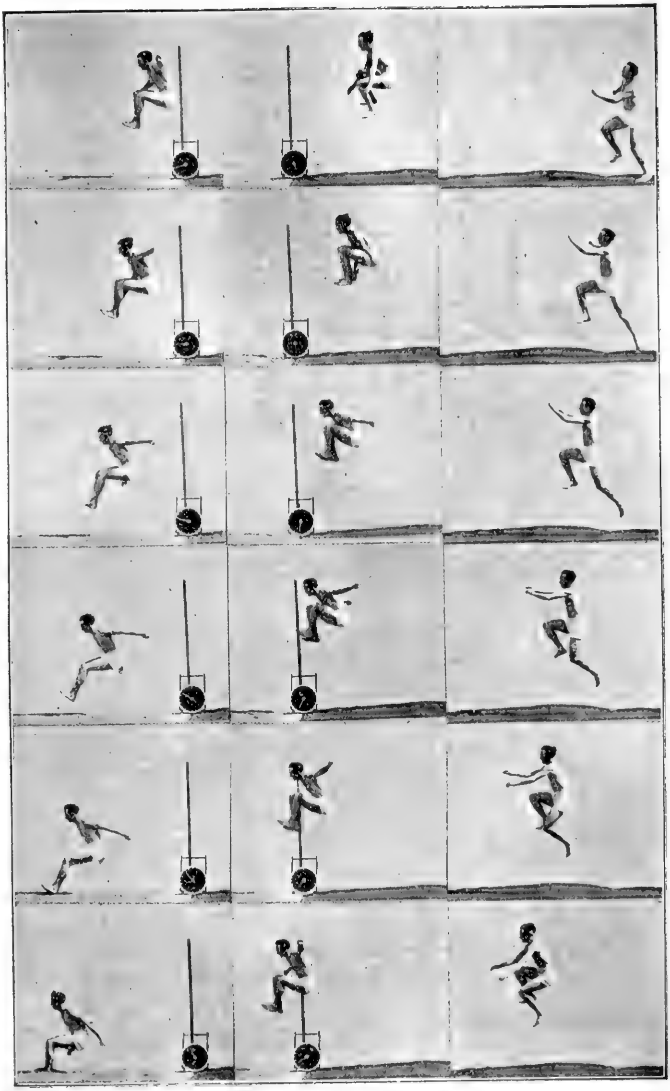

FIG. 4.—Long jump by Sweeney.

PROFESSOR WILHELM SCHUR.[1]

IT was with great regret that we had to announce last week the death of Prof. Wilhelm Schur, of Göttingen, a loss which deprives, not only astronomy of one of its most ardent and enthusiastic workers, but many of us of a kind and devoted friend. The loss will be felt personally by a great number of Britishers and Americans who have studied at the Göttingen University and who met Schur, not only in the lecture theatre and observatory, but at his private home.

Schur was born on April 15, 1846, and first took a great interest in astronomy at the Altona Observatory, where the director of the Observatory, Prof. A. C. Petersen, was one of his near relations. His first studies were commenced at Kiel in 1863, and three years later he migrated to Göttingen, where he graduated, his thesis being a computation of the orbit of the double star 70 *p* Ophiuchi after the new formula of Klinkerfues. Schur always took a great interest in after years in this double star, as is shown by later publications. Leaving the University, he made a tour for further study, working at Berlin under Auwers at the new reduction of Bradley's observations, and under Foerster at the Observatory. While at Berlin he was made assistant at the Geodetic Institute, and remained there until he was called (in 1873) by Winnicke to Strassburg. After spending some time there, he was made observer, and worked, as he had always done, with untiring zeal and energy. He was chosen to form part of the transit of Venus expedition in 1874, which set out for the Auckland Islands under the direction of Seeliger.

It was in connection with this work that Schur became so intimately familiar with the working and details of the heliometer, and since then he proved himself to be one of the greatest authorities, if not the greatest, upon this important instrument. Schur, however, was not content to restrict his energies to this instrument alone, but developed a many-sided interest for all the instruments at the observatory. Thus, to take two instances, he made a series of important lunar observations with the transit instrument of Cauchoix, and numerous observations of variable stars, and completed a minute investigation on the optical properties of different varieties of glass, before the construction of the large refractor.

In 1886 Schur was called to Göttingen to fill the chair of practical astronomy, which had become vacant owing to the death of Klinkerfues. The first few years spent there were devoted to the rebuilding of the observatory, the arrangement of the library, and the laborious computations and publication of Klinkerfues' observations. The observatory became the possessor of a fine new large Repsold heliometer, so that Schur was able to return again to his favourite instrument. In his hands and with his energy a great amount of useful work was accomplished, and he investigated more especially in the greatest detail the constants and many peculiar sources of error of the instrument.

Perhaps the most important of these researches was contained in the very complete work on the stars in the cluster of Præsepe, in which he brought together in a masterly way everything that is necessary for the reduction of heliometer observations. His most recent great work, and one which he laid before astronomers at the Heidelberg conference, was that relating to the triangulation of the star clusters h and χ Persei.

Up to the last, Schur sustained his interest in collecting and working up old observations, and in the past few years, under his guidance, Dr. Stichtenoth made a new reduction of Olbers' observations of comets, which appeared in 1898 as an appendix to Schilling's "Leben Olbers." More recently Schur was busy with collecting material of astronomical work done by astronomers in the province of Hanover, and the results of this study are already completed, but not yet published.

Although Schur was not among the favoured few to whose name some epoch-making discovery could be attached, yet his observations and reductions will endure as examples of exact and careful work and will prove both valuable and useful in future investigations.

WILLIAM J. S. LOCKYER.

[1] For most of the details in this notice I am indebted to a notice in the *Astronomische Nachrichten* (No. 3731).—W. J. S. L.

BARON DE LACAZE-DUTHIERS.

THE death of Prof. de Lacaze-Duthiers on July 21, in his eighty-first year, deprives the world of science of a renowned and energetic naturalist whose active life was devoted to the advancement of scientific knowledge and interests.

From an obituary notice in *La Nature* we learn that Henri de Lacaze-Duthiers was born at Montpezat (Lot-et-Garonne) on May 15, 1821. He began the study of medicine at Paris, but soon devoted himself to zoology, and in 1854 was appointed professor of zoology in the University of Lille. At his request he was afterwards entrusted by the Government with the task of studying the nature of corals on the Mediterranean coasts. He spent several months along the Algerian coast, and then returned to Paris with an abundance of material. His great work, the "Monographie du Corail," was the result of this expedition, and its publication inaugurated a new stage of appointments in his career. He was appointed maître de conférences at the Normal School in 1864, and in the following year became professor of zoology at the Paris Museum of Natural History. Three years later Lacaze-Duthiers passed from the Natural History Museum to the Sorbonne, where he accepted the chair of zoology, and finally, in 1871, he was elected a member of the Paris Academy of Sciences, and later became president of the Academy.

Among Lacaze-Duthiers' published volumes may be mentioned his "Histoire naturelle du corail," "Histoire de l'organisation et du développement des mœurs du Dentale" and "Le Monde de la mer et ses laboratoires." In 1873 he founded the *Archives de la zoologie expérimentale*, and he was the author of numerous papers and memoirs which have contributed to the development of zoology. The two Government stations of marine biology, established by the exertions of Lacaze-Duthiers, are memorials of his influence upon zoological science. The first was founded at Roscoff, in one of the most attractive and favourable collecting regions in Brittany, and has continued to grow in importance for more than a quarter of a century. As this station, however, could be serviceable during summer only, it gave rise to a smaller dependency of the Sorbonne in the southernmost part of France, on the Mediterranean, at Banyuls-sur-mer, which has the additional advantage of a Mediterranean fauna.

Many British and American students have been welcomed to these institutions and have enjoyed the advantages they afford. Describing the Roscoff laboratory several years ago, Mr. Bashford Dean said: "The stranger who writes to Prof. de Lacaze-Duthiers is accorded a work place which entitles him gratuitously to every privilege of the laboratory—his microscope, his reagents, even his lodging-room should a place be vacant. It seems, in fact, to be a point of pride with Prof. Lacaze-Duthiers that the stranger shall be welcomed to Roscoff and, upon entering the laboratory for the first time, feel as much at home as if he had been there a week." This liberal spirit was a characteristic of Lacaze-Duthiers; he was always ready to facilitate the study of nature by any means within his power, and right up to the time of his death he occupied himself with investigations of scientific problems. As a tribute of admiration for the good and useful work done by him in zoology, his pupils presented him with a magnificent engraved portrait of himself in 1887; and at a dinner given in his honour by the Scientia Club in 1890, M. Charles Richet, who presided, referred to him as "the conqueror of the sea and apostle of zoology." His pupils and colleagues were, in fact, deeply sensible of his great services to science, and lost no opportunity of expressing their esteem.

Lacaze-Duthiers worked in his laboratory at Banyuls up to a few days of his death, and almost up to his last hour his faculties were engaged in the extension of scientific knowledge. He was the animating spirit of French zoology and the mentor of many living naturalists. He devoted his life and his means to science, and worked for her interests without regard for fatigue or considerations of age. In announcing his death to the Paris Academy of Sciences, which adjourned the meeting of July 22 to show regard for him, M. Fouqué, the president, remarked:—"Son esprit était ouvert à toutes les nouveautés scientifiques, sa parole claire et facile, son enseignement plein d'entrain. Il aimait la discussion et savait en faire jaillir la lumière. Il laisse parmi nous le souvenir d'un Confrère érudit et laborieux, doué d'une prodigieuse activité, habile à résoudre les problèmes compliqués que soulève l'organisation du règne animal."

Not only France, but the whole scientific world is poorer by the death of so great a naturalist.

NOTES.

WE regret to see the announcement that Prof. Baron von Nordenskjöld, the renowned Arctic explorer, died at Stockholm on August 12.

ACCORDING to the Copenhagen correspondent of the *Temps*, the two Nobel scientific prizes of 200,000f. have been awarded to Prof. Finsen, of Copenhagen, for his treatment of lupus by light, and the Russian physiologist, M. Pawloff, for his works on nutrition.

THE Fifth International Congress of Zoology was opened at Berlin on Monday in the buildings of the Reichstag, the interior of which has been arranged for the convenience of the members of the congress. In the absence of the Crown Prince, who is the patron of the congress, the foreign delegates were welcomed by Prof. Moebius, the president, who moved that the assembly should send a telegram expressing profound sympathy and regret to the Emperor of Germany. This proposal was seconded by Prof. E. Perrier, of Paris, and was unanimously adopted. A telegram expressing thanks for the sympathy was received from the Emperor on Tuesday. Other speakers at the opening meeting were the Chief Burgomaster of Berlin, Herr Kirchner, and the Rector of Berlin University, Prof. Harnack. The meetings will be held throughout this week, and the congress will be concluded on Sunday with a visit to the biological station on Heligoland.

THE annual awards of prizes by the Reale Accademia dei Lincei, of Rome, are as follows:—The Royal prize for chemistry has been adjudged to the late Prof. Amerigo Andreocci for his researches on heterocyclic compounds and on the santonine group, and other papers. The Royal prize for philosophy and moral science has been adjudged to the late Prof. Carlo Giussani. In political science and jurisprudence no award has been made, and the same is true of the Santoro prize relating to agricultural zoology. The two prizes instituted by the Minister of Public Instruction in favour of teachers in secondary schools for work in natural science have been divided, awards being given to Profs. Liberto Fantappiè (Viterbo), Antonio Neviani (Rome), De Toni (Venice), and Giacomo Trabucco (Florence). Two "Ministerial" prizes of a similar character for philosophical and social sciences are awarded to Profs. Luigi Einaudi (Turin) and Aurelio Covotti (Palermo). At the special meeting of the Accademia at which these awards were made, an obituary discourse on the late Prof. Angelo Messedaglia was given by Signor Luigi Luzzatti, and an address was read by Signor Gerolamo Boccardo on science and social progress. A list of Prof. Messedaglia's writings is appended to the former discourse in the *Rendiconti delle Sedute solenni* containing the report of the meeting.

THE twelfth annual general meeting of the Institution of Mining Engineers will be held at Glasgow on September 3-6 under the presidency of Sir W. T. Lewis, Bart.

A REUTER telegram from Geneva states that a meeting of the International Association of Botanists was held in the University there on August 7. A number of foreign universities and societies, including the Universities of Oxford, Cambridge and Glasgow, and Trinity College, Dublin, were represented.

THE Paris correspondent of the *Chemist and Druggist* states that with a view to give an impetus to the study of applied chemistry in Paris, it has been decided to build additional laboratories at the Conservatoire des Arts et Métiers. The initial expense is estimated at 500,000f. (20,000*l.*), and the annual upkeep at something over 3000*l.* The laboratories will also be used for experiments in physics and mechanics.

THE *Times* records that the German South Polar expedition sailed from Kiel on Sunday by the steamer *Gauss.* Herr Rothe, Imperial Under-Secretary of State for the Interior, thanked the members of the expedition in the name of the Emperor and of Germany, and hoped that their labours would meet with complete success. Prof. von Drygalski, the leader of the expedition, replied on behalf of the expedition.

THE balloon in which M. Santos Dumont made his recent trial trips has met with an accident which has placed it beyond repair, so a new one is being constructed and will be ready by September 1. The new balloon will have nearly the same volume as the one that came to grief on August 8—34 metres in length and 6 metres in diameter in the centre—but, instead of being cylindrical, it will be ellipsoidal in shape, and the *ballonet*, instead of being at one end, will be placed in the middle.

THE wireless telegraph station established on the Nantucket lightship by the *New York Herald* enables passengers by incoming vessels equipped with the Marconi instruments to enter into communication with the American Continent and through it with the whole world from fourteen to sixteen hours earlier than is the case at present. The installation of the station is rapidly approaching completion. The *Lucania,* which sailed from Liverpool on Saturday last, will be the first Transatlantic liner to greet the New World with a wireless message sent from a ship at sea.

THE *Pioneer Mail* of Allahabad states that as a consequence of the continued fall in prices, the area under indigo in the North-West Provinces of India is rapidly falling. In 1900 there was a slight and temporary recovery, but during the present year there has again been a very marked decline. According to the preliminary statement received from the village accountants, the total area sown with indigo up to the middle of April this year amounts to 119,313 acres, as compared with 188,645 acres returned last year; while that reported to be irrigated from canals up to the end of May last is 78,894 acres, against 162,298 acres returned last year. The decrease in the former area amounts to about 37 per cent., in the latter to 50 per cent.

THE Society of German Engineers has decided to prepare and publish the trilingual technical dictionary proposed a year ago, and circulars inviting cooperation have been sent to technical societies and engineers likely to assist the project with suggestions and lists of words. Dr. Hubert Jansen has been appointed editor of this "Technolexicon," and an editorial office has been established at Berlin (N. W. 7), 49, Dorotheenstrasse. The dictionary will appear in three volumes, namely: vol. 1, German-English-French; vol. 2, English-German-French; and vol. 3, French-German-English. To make the work as complete as possible, it is hoped that many collaborators will collect technical words and expressions and send to the editor those which do not occur in an ordinary dictionary. A note-book for setting down such uncommon words and expressions which crop up in connection with engineering work will be sent to persons who are willing to assist the project. These words are acceptable even if the equivalents in the two other languages are not known. The editor would also be glad to receive references to, or copies of, good special dictionaries, technological text-books, price-lists and catalogues referring to any branches of industry or handicraft. We suggest that the printed pocket-books used by electricians, engineers, surveyors, architects and others contain a large number of technical terms for which equivalents in French and German are difficult to find. It is not clear from the prospectus whether the dictionary will include technical terms used in physics and chemistry as well as those which belong to engineering. If not, it will sometimes be difficult to distinguish between scientific and engineering terms. For instance, electrochemistry is an industry, so its technical terms will be included in the dictionary; but it is also a science, and its scientific terms should also be included. If the scope of the dictionary is made sufficiently broad to cover physical as well as engineering science, the work should be of value to students of foreign scientific literature.

THE *Meteorologische Zeitschrift* for July contains a very interesting and comprehensive article by Prof. H. Ebert, of Munich, on the phenomena of atmospheric electricity, considered from the standpoint of the theory of ions, or carriers of positive and negative electricity, generated by the medium of radiation. The electrification of a gas has, especially since the discovery of the Röntgen rays, become a subject of fundamental importance, and has occupied the attention of several physicists, more particularly Messrs. Elster and Geitel, of Wolfenbüttel, and Mr. Wilson, of Cambridge, who have independently arrived at important and very similar results. They have also greatly improved the necessary apparatus and methods of measurement, by which means they have been able to show the connection between the electric conductibility of the air and artificially ionised gases. The following are some of the results deduced from the ionic theory. (1) The greater the solar radiation the less is the electric potential generally observed. (2) The ions generated at a great altitude are maintained for a certain time in the air and participate in its movements. (3) Dust, and especially aqueous vapour, obstruct the mobility of the ions, and therefore diminishes the conductibility of the air. (4) Negative ions move at greater speed than the positive. (5) The ions form condensation nuclei which, in the case of supersaturated damp air, are exhibited as fog or cloud; hence the negative ions are more suitable for forming nuclei than the positive. The subject of the condensation properties of ionised air has been carefully investigated by Mr. Wilson, and some of the results have been published in the *Philosophical Transactions* and other scientific papers.

MR. W. L. MOORE, chief of the U.S. Weather Bureau, has given an official opinion upon the value of cannonading as a means of preventing the fall of hail. The following extracts from the *Monthly Weather Review* show that he does not attach any importance to the Stiger method of bombardment, now so widely adopted in Italy, southern Austria and southern France:—"It consists essentially in sending vortex rings of smoke and air upward toward the clouds; but the most powerful Stiger cannon that have yet been employed do not send these rings higher than 1200 feet above the ground, and, therefore, utterly fail to reach the clouds. On this account the distinguished Austrian meteorologist, J. M. Pernter, has maintained that if there is any virtue whatever in the idea, the experimenters must use much more powerful apparatus. But there is no satisfactory evidence that the cannonading or the vortices had any influence whatever on the hail. Both theory and practice agree in this conclusion. Theoretically it was imagined by Mr. Stiger that hail is formed in quiet spots in the atmosphere where the atmospheric moisture could crystallise out in large crystals in a manner analogous to the formation of large crystals of salt in liquid solution. But this is a very foolish notion; there are no such quiet spots in the atmosphere, and hailstones are not crystals, but masses of ice, with only a feeble or partial crystalline structure. Even the perfect crystals of the snowflakes are formed in the midst of rapidly-moving air, so that the whole theoretical basis for hailstorm cannonading falls to the ground. . . . After examining all that has been published during the past two years, my conviction is that we have here to do with a popular delusion as remarkable as is the belief in the effect of the moon on the weather. The uneducated peasantry of Europe seem to be looking for something miraculous. They would rather believe in cannonading as a means of protection and spend on it abundance of money, time and labour, than adopt the very simple expedient of mutual insurance against the losses that must inevitably occur."

NO. 169 of the *Bulletin* of the French Physical Society contains a brief note on some experiments by Mr. L. Benoist on the transparency of bodies for Röntgen rays. The method adopted consists in plotting curves in which abscissæ represent atomic weights and ordinates represent the corresponding transparencies. In this way it is possible to establish the existence of a functional relation between the atomic weight and the transparency, and, further, to discriminate between different kinds of rays which give different curves.

Bulletin No. 98 of the U.S. Department of Agriculture consists of reports by Drs. Atwater and Sherman and by Mr. R. C. Carpenter on food consumption and metabolism, and on the mechanical efficiency of bicyclists. The experiments were made during a six days' bicycle race, and consisted in analytical determinations of the heat equivalent of the food consumed on the one hand, and estimates of the work done as deduced from calculations of air resistance and wheel resistance on the other hand. The experiments show, among other results, the great amount of easily-digested food required by the competitors, the greatly increased metabolism of nitrogen, the large amount of work done per day by the athletes in this competition, which averaged in one case more than ten million foot-pounds, or more than five times the average daily work of a man as estimated by Dr. Thurston, and, lastly, the high efficiency of the human subject as a motor, for which the authors obtain estimates ranging as high as 45 and 60 per cent. In regard to the accuracy of the determinations, a good deal of uncertainty must exist as to the amount of energy derived from combustion of body tissue by the bicyclists, and also as to the actual resistance overcome, which latter could best be determined by dynamometer observations. The determinations of the efficiency of the human subject have an interesting bearing on the question as to whether organic life is subject to the second law of thermodynamics or Maxwell's "demons" actually exist in the animal kingdom. We should also like to see dietary studies taken in periods of exceptional brain activity, as, for example, on subjects sitting for a competitive examination.

AN interesting and useful pamphlet has recently been issued by Mr. A. Hilger, containing full description and details of manipulation of the Michelson Echelon Grating. Many of the principal Universities of Europe have been provided with this very powerful means of spectroscopic determination, and the experience gained has been sufficient to permit the designing of a standard type of instrument. In this the thickness of each plate is 10 mm., and the width of each step 1 mm. The progressive precision in the working of the plates has enabled Mr. Hilger to avoid the considerable loss of light which was caused, in the original instruments, by the plates not being mechanically clamped together. They are now held in position by a screwed frame, which can be so adjusted that no distortion is perceptible, while the increase in brilliancy of the spectra is very noticeable.

WIRELESS telegraphy is in use upon ships engaged in the naval manœuvres, and it enables a battleship to communicate with a cruiser fifty or sixty miles away with greater ease than the same ship could be communicated with at a distance of ten miles in clear weather a year or two ago. But the *Times* special correspondent with one of the fleets remarks that the method, although independent of the weather, is still subject to one very serious drawback. The communication is not, and cannot be, a private or exclusive one, except so far as the messages are transmitted in cipher. Even so, every ship within range which is fitted with the necessary apparatus can take in the message, and if an enemy's ship is within range she can, by setting her own apparatus at work, break up the message and render it unintelligible. It is perhaps more politic to take it in clandestinely and work out the cipher—a thing which it is seldom very difficult to do and never altogether impossible if sufficient cipher material be obtained and sufficient time be devoted to the task. The moral is to employ as difficult a cipher as possible and to change it as soon as there is any reason to suspect the enemy has discovered it. But, even so, wireless telegraphy as at present practised is full of limitations and pitfalls which only experience can eliminate. It will never be quite satisfactory for war purposes until the transmitting instrument can be so adjusted as to emit vibrations of different pitch at the will of the operator and the receiving instrument rendered sensitive only to vibrations of a given pitch at a given moment. In that case, every ship in a fleet could have its own pitch and be sensitive only to messages addressed to itself in that particular pitch, while, unless an enemy within range happened to be attuned to the same pitch at the moment—a very unlikely contingency if the pitch were changeable at will—he would be powerless to intercept the message.

THE electrolytic dissociation theory of Arrhenius is severely criticised by Prof. Kahlenberg in a paper in the *Bulletin* of the University of Wisconsin (No. 47, February 1901), in which a great deal of experimental evidence in contradiction to the theory is brought forward. Prof. Kahlenberg has measured the conductivity of a number of electrolytes at 0° and 95° and calculated the degree of dissociation from these measurements as well as from determinations of the lowering of the freezing point and rise of the boiling point. The two sets of results he has thus obtained are far from concordant, from which he concludes that the dissociation theory is incorrect and doomed to early extinction. This theory, even though it has not met with universal acceptance, is not, we think, to be so easily overthrown, especially until some more satisfactory and fruitful alternative hypothesis is put forward to take its place. It is interesting to note that another American professor, Prof. H. C. Jones, of the Johns Hopkins University, is now contributing a series of valuable "Chapters in Electrochemistry" to the *Electrical Review* of New York, in which the subject is treated entirely from the point of view of the ionic theory, of which Prof. Jones is a vigorous adherent.

THE *Times* correspondent at Simla states that since the Pasteur Institute at Kasauli was opened a year ago, 321 patients have been treated, including 96 from the British Army and 50 European civilians. Not a single failure has occurred among the Europeans, but two natives died. Both of the latter had been badly bitten and arrived too late to be saved. The complete success of the Institute, which is under the charge of Major Semple, of the Army Medical Service, means a great saving to the Government, as soldiers need no longer be sent to Paris for treatment. It is hoped that funds will be provided to make possible the preparation of anti-toxins for enteric, snakebite and tetanus.

IT is a matter for regret when familiar names like Octopus have to disappear from the effective list, yet, according to Mr. Hoyle (*Manchester Memoirs*, xlv. No. 9), this must be replaced by Polypus on the ground of priority. In the same communication, the question is raised whether the name Histiopsis is preoccupied by Histiops—a point on which experts differ. In No. 4 of the same serial, Mr. Hoyle gives an instance of the danger of making genera and species on imperfect specimens. Part of a cuttlefish taken from a sperm-whale's stomach was referred to a new genus on account of its being apparently covered with regularly arranged quadrangular scales. Specimens recently acquired suggest that the appearance in question was due to decomposition.

THE secretary of the British South Africa Company has sent us a copy of the "Reports on the Administration of Rhodesia, 1898-1900," issued by the Company. One section is devoted to "Notes on the Fauna and Flora of North-eastern Rhodesia," by Mr. C. P. Chesnaye. From this we learn that the prospect of the survival in considerable numbers of the larger mammals and reptiles in the district to the west of Loangwa and in the swamps of Bangweolo and Mweru is very hopeful. The elephant is still met with in large herds, owing to its living for the greater part of the year in almost inaccessible swamps. The formation of a game-reserve to the east of Lake Mweru will probably largely aid in the preservation of this and other species, as it is believed that the elephants now hunted by Swahili traders to the south of Tanganyika will gradually retire to the reserve. Rhinoceroses are still fairly numerous, while hippopotamuses abound. The rinderpest which swept over the country in 1893 decimated the buffalo, eland and lichi antelope, but the country is gradually recovering from the scourge, and most districts are now very rich in game of all kinds, especially roan antelope, eland, Lichtenstein's hartebeest, puku, lichi and zebra. A few of the beautiful sable antelope still survive in the Mweru district, and around the north end of the lake the swamp-loving sitatunga antelope is plentiful. The rare sassabi hartebeest is restricted to a small area west of Lake Bangweolo. The dreaded tsetse-fly is stated to be prevalent in the valley of the Loangwa from the Zambesi to the confines of the Nyasa plateau, as well as in one other district, but to be absent from the greater portion of the Bangweolo country. Whether the latter part of the statement is true requires confirmation, but most of the territory seems free from "fly."

WE have received from the New Mexico College of Agriculture *Bulletin* No. 37, containing "Notes on the Food of Birds," by Mr. T. D. A. Cockerell. This is chiefly of local interest.

IN the *Bollettino* of the Italian Geographical Society, Signor Cesare Cipolletti continues his papers on the Argentine Republic, dealing with the regions of the Rio Negro and the Rio Colorado. Appended to a note on the Italian sphere of influence in Africa is a map showing the boundaries of the colony of Eritrea, compiled from official sources.

A PAPER by Herr S. Puchleitner in the *Mittheilungen* of the Vienna Geographical Society, on the glacial period in the Southern Carpathians, gives an excellent summary of recent research in this region, and more especially of de Martonne's valuable work on cirques. Dr. Kurt Hassert publishes an account of his journey through Montenegro during the summer of 1900, in the same number.

Petermann's Mittheilungen contains an article on the magnetic work to be undertaken by the German South Polar Expedition, by Dr. Bidlingmaier, the meteorologist and magnetician of the expedition. It includes the official programme of observations on the term days, and of the international scheme of cooperation, whereby it is hoped to obtain synoptic charts showing the magnetic condition of the whole globe on these days. Dr. Hans Gazert, the doctor of the Expedition, also contributes a paper on the bacteriological problems to be investigated.

A NUMBER of the *Abhandlungen* of the Vienna Geographical Society, just issued, contains a paper on the contrasts in climate on the east and west coast regions of continents in extra-tropical latitudes, by Dr. Ludwig Coellen. The author arranges the results of observations, chiefly obtained from tables published by Buchan, Hann and Woeikof, in such a way as to clearly bring out the salient points of difference; but it may be doubted if the selection of individual stations on which his generalisations are based is always satisfactory. We note that the direct influence of ocean currents is properly relegated to a secondary place.

IN a former paper on barisâl guns, &c., in the province of Umbria (*Boll. Soc. Sismol. Ital.*, vol. iii. 1897, pp. 222–234), Dr. Cancani attributes these phenomena to endogenous causes. He continues the subject in the last number of the same journal (vol. vii. 1901, pp. 23–47), describing similar noises which have been observed in the districts round Isernia and Cosenza and in Umbria and Latium. In the latter case he argues that the sounds were neither of artificial nor of atmospheric origin; and, as slight tremors were noticed in some instances to accompany them, his views receive considerable support from the recent observations.

MEMOIRS and notes upon many aspects of polar exploration are included in the "Antarctic Manual" prepared for the use of the members of the British Antarctic expedition. Mr. George Murray, F.R.S., is the editor of the manual, and Sir Clements Markham, K.C.B., contributes a preface in which he surveys the contents, and remarks that the volume "is presented to the expedition by the president and council of the Royal Geographical Society," so that the Royal Society is not officially concerned with the work. Among the subjects of papers in the volume are:—ice nomenclature, astronomical data, tidal observations, pendulum observations, terrestrial magnetism, climate, wave observations, the aurora, atmospheric electricity, chemical and physical notes, geology, volcanoes and volcanic action, ice observations, the collection of rocks and minerals, zoology, botany, sledge-travelling, geography, and an Antarctic bibliography. The manual thus contains in a compact form practically all that is known about South Polar regions, and also records of experience in Arctic exploration.

THE additions to the Zoological Society's Gardens during the past week include a Crab-eating Raccoon (*Procyon cancrivorus*) from South America, presented by Mr. George Lancefield; a Wild Swine (*Sus scrofa*) from Persia, presented by Mr. B. T. Ffinch; a Cardinal Grosbeak (*Cardinalis virginianus*), two Bluebirds (*Sialia wilsoni*) from North America, presented by Colonel Ashburner; a Golden Eagle (*Aquila chrysaëtos*) from Scotland, presented by Mr. J. Monro Walker; two Stone Curlews (*Ædicnemus scolopax*), British, presented by Mr. A. E. Chaplin; an Orange-cheeked Waxbill (*Estrelda melpoda*) from West Africa, presented by Mr. W. S. Primley; a Kinkajou (*Cercoleptes caudivolvulus*) from South America, deposited; a Hoffmann's Sloth (*Cholopus hoffmanni*) from Panama, purchased.

OUR ASTRONOMICAL COLUMN.

ENCKE'S COMET.—A telegram sent out from Harvard College Observatory announces that the first observation of this periodic comet was made by Prof. Wilson at Northfield, on Monday evening, August 5.

The determination of position was as follows:—

$$\left.\begin{array}{l}\text{R.A.} = 6\text{h. } 2\text{m. } 2\cdot8\text{s.}\\ \text{Decl.} = +31^\circ\ 42'\ 30''\end{array}\right\}(1901).\quad \begin{array}{c}\text{August 5d. 9h. 25m. 3s.}\\ \text{G.M.T.}\end{array}$$

OBSERVATIONS OF MARS.—In the *Bulletin de la Soc. Astronomique de France* (1901, pp. 345–355), MM. Flammarion and Antoniadi give an account of their new observations of the planet Mars made at the Juvisy Observatory during the period 1900 October 23 and 1901 July 6. Two charts are given, one showing the northern hemisphere as a polar projection, the other giving the zone from $+80^\circ$ to -50° lat. on Mercator's projection.

Tables are given showing the varying dimensions of the North Polar snow-cap, which at the summer solstice had a diameter of about twenty degrees. The charts are described in detail, showing the differences from former observations. Attention is again drawn to the half-tone shading which apparently extends over the northern hemisphere from the pole to latitude 45°, limited towards the south by the region containing the canali.

At Juvisy, fifty canali have been seen, forty-six of which agree with the observations of Schiaparelli, and one from the list of Cerulli. Only three cases of gemination have been noticed, the most prominent being Cerberus and Casius, which were visible without difficulty. The Styx was also suspected of duplicity, but the components were not sharply separated.

VARIATIONS OF THE MAGNETIC NEEDLE.—M. Souleyre commences a discussion of the possible causes of the variations of the magnetic needle, and in his first article outlines the production of currents and other disturbances in the solar corona by the action of the planets, these reacting on the supposed electrical constitution of the corona and other solar surroundings. The extension of the theory to explain the periodicity of sunspots, terrestrial magnetic storms and auroræ is then presented, special attention being given to the effect of planetary disturbance (*Bull. Soc. Ast. de France*, 1901, pp. 362–370).

VARIATION OF EROS.—Supplementing his recent note, M. André furnishes a few further particulars concerning the form of light-curve and amplitude of the determined variation, in *Comptes rendus* (cxxxiii. pp. 324–326). When observed on the same evening, the minima of two orders were not quite identical. The form of the light-curve in the neighbourhood of the minima did not sensibly change during the observations, but a considerable degree of change has occurred about the points of maxima. A table is included showing the amplitudes of the variation observed on nineteen evenings during February, March and April, 1901, ranging from 2·0 magnitudes to zero.

ORBITS OF ALGOL VARIABLES, RR PUPPIS AND V PUPPIS.—Dr. A. W. Roberts has computed the characteristic features of the orbits of these two variables from observations secured at his private observatory, Lovedale, South Africa. Of the two variables, V Puppis is specially interesting from the fact that it is a spectroscopic binary, so that more refined measurements in the line of sight may possibly enable the absolute masses of the system to be determined.

RR Puppis.—

$$\left.\begin{array}{l}\text{R.A.} = 7\text{h. } 43\text{m. } 31\text{s.}\\ \text{Decl.} = -41^\circ\ 7'\cdot6\end{array}\right\}(1900\cdot0).$$

This star has been under observation for nearly twelve months, and some 200 measures obtained. The period adopted is

6d. 10h. 19·6m.,

and the light-curve based on this value is given, with an enlarged diagram of the part near minimum. The curve is almost identical in form with that of S Velorum. Other details are as follows:—

Limits of variation are 9·1 and 10·8 magnitude.
Duration of increasing or decreasing phase = 4h. 15m.
Stationary period at minimum = 8h. 30m.

The system thus apparently consists of two bodies, one of which is *three* times the diameter of the other. The smaller star is nearly twice as bright as the larger one, and the distance between their circumferences is about two-thirds of the radius of the orbit. The density of the system is probably not more than one-sixth that of the sun.

V Puppis.

$$\left.\begin{array}{l}\text{R.A.} = 7\text{h. } 55\text{m. } 22\text{s.} \\ \text{Decl.} = -\ 48^\circ\ 58'\cdot 4\end{array}\right\}(1900\cdot 0).$$

This star differs from the preceding one in that it consists of two bodies of about equal size and brightness. The mean period, as deduced from the light variation, is

1d. 10h. 54m. 26·7s.

The light-curve of this star is strikingly similar to that of U Pegasi, showing double and *unequal minima*, and double and *equal maxima*.

Prof. Pickering, however, from spectroscopic determinations, deduces a period of

3d. 2h. 46m.

From the peculiarity of there being no stationary period at either maximum, Dr. Roberts infers that the two component stars revolve around each other *in actual contact*. Under such conditions, both bodies would most probably undergo distortion. The value derived for the density of V Puppis is 0 07 that of the sun, the orbit being circular.

POLISH.[1]

THE lecture commenced with a description of a home-made spectroscope of considerable power. The lens, a plano-convex of 6 inches aperture and 22 feet focus, received the rays from the slit, and finally returned them to a pure spectrum formed in the neighbourhood. The skeleton of the prism was of lead; the faces, inclined at 70°, were of thick plate-glass cemented with glue and treacle. It was charged with bisulphide of carbon, of which the free surface (of small area) was raised above the operative part of the fluid. The prism was traversed twice, and the effective thickness was 5½ inches, so that the resolving power corresponded to 11 inches, or 28 cm., of CS_2. The liquid was stirred by a perforated triangular plate, nearly fitting the prism, which could be actuated by means of a thread within reach of the observer. The reflector was a *flat*, chemically silvered in front.

So far as eye observations were concerned, the performance was satisfactory, falling but little short of theoretical perfection. The stirrer needed to be in almost constant operation, the definition usually beginning to fail within about twenty seconds after stopping the stirrer. But although the stirrer was quite successful in maintaining uniformity of temperature as regards *space, i.e.* throughout the dispersing fluid, the temperature was usually somewhat rapidly variable with *time*, so that photographs requiring more than a few seconds of exposure showed inferiority. In this respect a grating is more manageable.

The lens and the faces of the prism were ground and polished (in 1893) upon a machine kindly presented by Dr. Common. The flat surfaces were tested with a spherometer, in which a movement of the central screw through 1/100000 inch could usually be detected by the touch. The external surfaces of the prism faces were the only ones requiring accurate flatness. In polishing, the operation was not carried as far as would be expected of a professional optician. A few residual pittings, although they spoil the appearance of a surface, do not interfere with its performance, at least for many purposes.

In the process of grinding together two glass surfaces, the particles of emery, even the finest, appear to act by *pitting* the glasses, *i.e.* by breaking out small fragments. In order to save time and loss of accuracy in the polishing, it is desirable to carry the grinding process as far as possible, using towards the close only the finest emery. The limit in this direction appears to depend upon the tendency of the glasses (6 inches diameter) to *seize*, when they approach too closely, but with a little care it is easy to attain such a fineness that a candle is seen reflected at an angle of incidence not exceeding 60°, measured as usual from the perpendicular.

The fineness necessary, in order that a surface may reflect and refract regularly without diffusion, viz. in order that it may appear *polished*, depends upon the wave-length of the light and upon the angle of incidence. At a grazing incidence all surfaces behave as if polished, and a surface which reflects red light pretty well may fail signally when tested with blue light at the same angle. If we consider incidences not too far removed from the perpendicular, the theory of gratings teaches that a regularly corrugated surface behaves as if absolutely plane, provided that the *wave-length* of the corrugations is less than the wave-length of the light, and this without regard to the *depth* of the corrugations. Experimental illustrations, drawn from the sister science of acoustics, were given. The source was a bird-call from which issued vibrations having a wave-length of about 1·5 cm., and the percipient was a high-pressure sensitive flame. When the bird-call was turned away, the flame was silent, but it roared vigorously when the vibrations were reflected back upon it from a plate of glass. A second plate, upon which small pebbles had been glued so as to constitute an ideally rough surface, acted nearly as well, and so did a piece of tin plate suitably corrugated. In all these cases the reflection was *regular*, the flame becoming quiet when the plates were turned out of adjustment through a very small angle. In another method of experimenting the incidence was absolutely perpendicular, the flame being exposed to both the incident and the reflected waves. It is known that under these circumstances the flame remains quiescent at the *nodes* and flares most vigorously at the *loops*. As the reflector is drawn slowly back, the flame passes alternately through the nodes and loops, thus executing a cycle of changes as the reflector moves through *half* a wave-length. The effects observed were just the same whether the reflector were smooth or covered with pebbles, or whether the corrugated tin plate were substituted. All surfaces were smooth *enough* in relation to the wave-length of the vibration to give substantially a specular reflection.

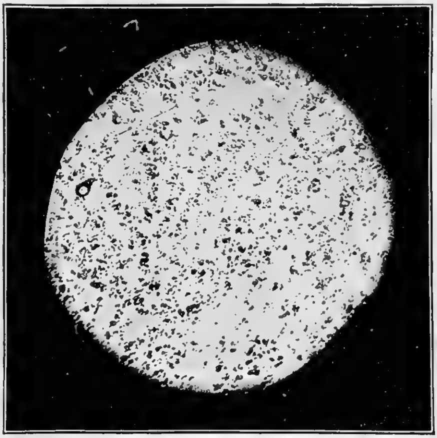

FIG. 1.

Finely ground surfaces are still too coarse for perpendicular specular reflection of the longest visible waves of light. Here the material may be metal, or glass silvered chemically on the

[1] A discourse delivered at the Royal Institution on Friday, March 29, by the Right Hon. Lord Rayleigh, F.R.S.

face subsequently to the grinding. But experiment is not limited by the capabilities of the eye; and it seems certain that a finely ground surface would be smooth enough to reflect without sensible diffusion the longest waves, such as those found by Rubens to be nearly 100 times longer than the waves of red light. An experiment may be tried with radiation from a Leslie cube containing hot water, or from a Welsbach mantle (without a chimney). In the lecture the latter was employed, and it fell first at an angle of about 45° upon a finely ground flat glass silvered in front. By this preliminary reflection, the radiation was purified from waves other than those of considerable wave-length. The second reflection (also at 45°) was alternately from polished and finely ground silvered surfaces of the same size, so mounted as to permit the accurate substitution of the one for the other. The heating-power of the radiation thus twice reflected was tested with a thermopile in the usual manner. Repeated comparisons proved that the reflection from the ground surface was about 0·76 of that from the polished surface, showing that the ground surface reflected the waves falling upon it with comparatively little diffusion. A slight rotation of any of the surfaces from their proper positions at once cut off the effect. It is probable that the device of submitting radiation to preliminary reflections from one or more merely ground surfaces might be found useful in experiments upon the longest waves.

FIG. 2

In view of these phenomena we recognise that it is something of an accident that polishing processes, as distinct from grinding, are needed at all; and we may be tempted to infer that there is no essential difference between the operations. This appears to have been the opinion of Herschel,[1] whom we may regard as one of the first authorities on such a subject. But although, perhaps, no sure conclusion can be demonstrated, the balance of evidence appears to point in the opposite direction. It is true that the same powders may be employed in both cases. In one experiment a glass surface was polished with the same emery as had been used effectively a little earlier in the grinding. The difference is in the character of the backing. In grinding, the emery is backed by a hard surface, *e.g.* of glass, while during the polishing the powder (mostly rouge in these experiments) is imbedded in a comparatively yielding substance, such as pitch. Under these conditions, which preclude more than a moderate pressure, it seems probable that no pits are formed by the breaking out of fragments, but that the material is worn away (at first, of course, on the eminences) almost molecularly.

The progress of the operation is easily watched with a microscope, provided, say, with a ½-inch object-glass. The first few minutes suffice to effect a very visible change. Under the microscope it is seen that little facets, parallel to the general plane of the surface, have been formed on all the more prominent eminences.[1] The facets, although at this stage but a very small fraction of the whole area, are adequate to give a sensible specular reflection, even at perpendicular incidence. On one occasion five minutes' polishing of a rather finely ground glass surface was enough to qualify it for the formation of interference bands, when brought into juxtaposition with another polished surface, the light being either white or from a soda flame; so that in this way an optical test can be applied almost before the polishing has begun.[2]

As the polishing proceeds, the facets are seen under the microscope to increase both in number and in size, until they occupy much the larger part of the area. Somewhat later the

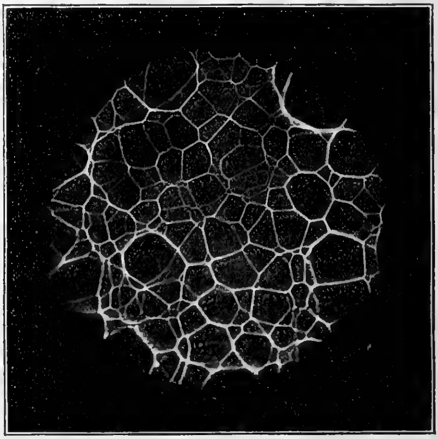

FIG. 3

parts as yet untouched by the polisher appear as pits, or spots, upon a surface otherwise invisible. Fig. 1 represents a photograph of a surface at this stage taken with the microscope. The completion of the process consists in rubbing away the whole surface down to the level of the deepest pits. The last part of the operation, while it occupies a great deal of time and entails further risk of losing the "truth" of the surface, adds very little to the effective area or to the intensity of the light regularly reflected or refracted.

Perhaps the most important fact taught by the microscope is that the polish of individual parts of the surface does not improve during the process. As soon as they can be observed at all, the facets appear absolutely structureless. In its subsequent action the polishing tool, bearing only upon the parts already polished, extends the boundary of these parts, but does not enhance their quality. Of course, the mere fact that no structure can be perceived does not of itself prove that pittings may not be taking place of a character too fine to be shown by

[1] "Enc. Met.," Art. Light, p. 477, 1830: "The intensity and regularity of reflection at the external surface of a medium is found to depend, not merely on the nature of the medium, but very essentially on the degree of smoothness and polish of its surface. But it may reasonably be asked how any regular reflection can take place on a surface polished by art, when we recollect that process of polishing is, in fact, nothing more than grinding down large asperities into smaller ones by the use of hard gritty powders, which, whatever degree of mechanical comminution we may give them, are yet vast masses, in comparison with the ultimate molecules of matter, and their action can only be considered as an irregular tearing up by the roots of every projection that may occur in the surface. So that, in fact, a surface artificially polished must bear somewhat of the same kind of relation to the surface of a liquid, or a crystal, that a ploughed field does to the most delicately polished mirror, the work of human hands."

[1] The interpretation is facilitated by a thin coating of aniline dye which attaches itself mainly to the hollows.

[2] With oblique incidence, as in Talbot's experiments (see *Phil. Mag.*, xxviii. p. 191, 1889), achromatic bands may be observed from a surface absolutely unpolished, but this disposition would not be favourable for testing purposes.

a particular microscope or by any possible microscope. But so much discontinuity, as compared with the grinding action, has to be admitted in any case that one is inevitably led to the conclusion that in all probability the operation is a molecular one, and that no coherent fragments containing a large number of molecules are broken out. If this be so, there would be much less difference than Herschel thought between the surfaces of a polished solid and of a liquid.

Several trials have been made to determine how much material is actually removed during the polishing of glass. In one experiment a piece 6 inches in diameter, very finely ground, was carefully weighed at intervals during the process. Losses of ·070, ·032, ·045, ·026, ·032 gm. were successively registered, amounting in all to ·205 gm. Taking the specific gravity of the glass as 3, this corresponds to a thickness of $3 \cdot 6 \times 10^{-4}$ cm., or to about 6 wave-lengths of mean light, and it expresses the distance between the original *mean* surface and the final plane. But the polish of this glass, though sufficient for most practical purposes, was by no means perfect. Probably the 6 wave-lengths would have needed to be raised to 10 in order to satisfy a critical eye. It may be interesting to note for comparison that, in the grinding, one charge of emery, such as had remained suspended in water for seven or eight minutes, removed a thickness of glass corresponding to 2 wave-lengths.

In other experiments the thickness removed in polishing was determined optically. A very finely ground disc was mounted in the lathe and polished locally in rings. Much care was needed to obtain the desired effect of a ring showing a continuously increasing polish from the edges inwards. To this end it was necessary to keep the polisher (a piece of wood covered with resin and rouge) in constant motion, otherwise a number of narrow grooves developed themselves.

The best ring was about half an inch wide. When brought into contact with a polished flat and examined at perpendicular incidence with light from a soda flame, the depression at its deepest part gave a displacement of three bands, corresponding to a depth of $1\frac{1}{2}\lambda$. On a casual inspection this central part appeared well polished, but examination under the microscope revealed a fair number of small pits. Further working increased the maximum depth to $2\frac{1}{2}\lambda$, when but very few pits remained. In this case, then, polish was effected during a lowering of the mean surface through 2 or 3 wave-lengths, but the grinding had been exceptionally fine.

It may be well to emphasise that the observations here recorded relate to a *hard* substance. In the polishing of a soft substance, such as copper, it is possible that material may be loosened from its original position without becoming detached. In such a case pits may be actually filled in, by which the operation would be much quickened. Nothing suggestive of this effect has been observed in experiments upon glass.

Another method of operating upon glass is by means of hydrofluoric acid. Contrary to what is generally supposed, this action is extremely regular, if proper precautions are taken. The acid should be weak, say one part of commercial acid to two hundred of water, and it should be kept in constant motion by a suitable rocking arrangement. The parts of the glass not intended to be eaten into are, as usual, protected with wax. The effect upon a polished flat surface is observed by the formation of Newton's rings with soda light. After perhaps three-quarters of an hour, the depression corresponds to half a band, *i.e.* amounts to $\frac{1}{4}\lambda$, and it appears to be uniform over the whole surface exposed. Two pieces of plate glass, 3 inches square, and flat enough to come into fair contact all over, were painted with wax in parallel stripes and submitted to the acid for such a time, previously ascertained, as would ensure an action upon the exposed parts of $\frac{1}{4}\lambda$. After removal of the wax, the two plates, crossed and pressed into contact so as to develop the colours, say of the second order, exhibited a chess-board pattern. Where two uncorroded, or where two corroded, parts are in contact, the colours are nearly the same, but where a corroded and an uncorroded surface overlap, a strongly contrasted colour is developed. The combination lends itself to lantern projection, and the pattern upon the screen [shown] is very beautiful, if proper precautions are taken to eliminate the white light reflected from the first and fourth surfaces of the plates.

In illustration of the action of hydrofluoric acid, photographs [1] were shown of interference bands as formed by soda light between glass surfaces, one optically flat and the other ordinary plate, upon which a drop of dilute acid had been allowed to stand (Fig. 2) Truly plane surfaces would give bands straight, parallel and equidistant.

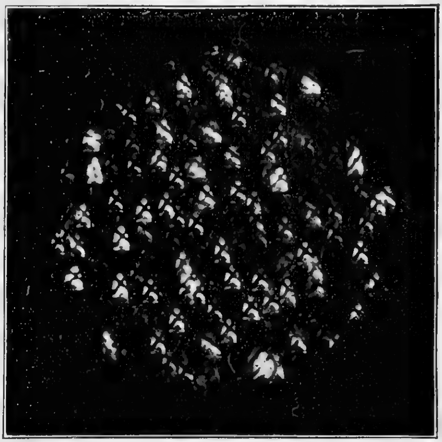

FIG. 4.

Hydrofluoric acid has been employed with some success to correct ascertained errors in optical surfaces. But while improvements in actual optical performance have been effected, the general appearance of a surface so treated is unprepossessing. The development of latent scratches has been described on a former occasion.[2]

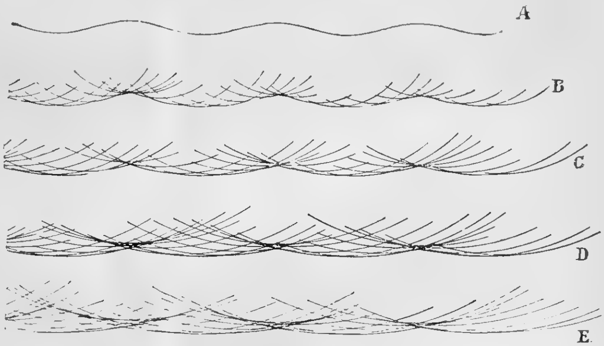

FIG. 5.

A second obvious application of hydrofluoric acid has hitherto been less successful. If a suitable stopping could be

[1] The plates were sensitised in the laboratory with cyanine.
[2] *Proc.* Roy. Inst., March, 1893.

found by which the deeper pits could be protected from the action, corrosion by acid could be used in substitution for a large part of the usual process of polishing.

In connection with experiments of this sort, trial was made of the action of the acid upon finely ground glass, such, for example, as is used as a backing for stereoscopic transparencies, and very curious results were observed. For this purpose the acid may conveniently be used much stronger, say one part of commercial acid to ten parts of water, and the action may be prolonged for hours or days. The general appearance of the glass after treatment is smoother and more translucent, but it is only under the microscope that the remarkable changes which the surface has undergone become intelligible. Fig. 3 is from a photograph taken in the microscope, the focus being upon the originally ground surface itself. The whole area is seen to be divided into cells. These cells increase as the action progresses, the smaller ones being, as it were, eaten up by the bigger. The division lines between the cells are *ridges*, raised above the general level, and when seen in good focus appear absolutely sharp. The general surface within the cells shows no structure, being as invisible as if highly polished.

That each cell is, in fact, a concave lens, forming a separate image of the source of light, is shown by slightly screwing out the object-glass. Fig. 4 was taken in this way from the same surface, the source of light being the flame of a paraffin lamp, in front of which was placed a cross cut from sheet-metal.

The movement required to pass from the ridge to the image of the source, equal to the focal length (f) of the lens, may be utilised to determine the depth (t) of a cell. In one experiment the necessary movement was ·005 inch. The semi-aperture (y) of the "lens" was ·0015 inch, whence by the formula $y^2=ft$, we find $t=\cdot 00045$ inch. This represents the depth of the cell, and it amounts to about 8 wave-lengths of yellow light.

The action of the acid seems to be readily explained if we make the very natural supposition that it eats in everywhere, at a fixed rate, normally to the actual surface. If the amount of the normal corrosion after a proposed time be known, the new surface can be constructed as the "envelope" of spheres having the radius in question and centres distributed over the old surface. Ultimately, the new surface becomes identified with a series of spherical segments having their centres at the deeper pits of the original surface. The construction is easily illustrated in the case of two dimensions. In the figure (Fig. 5) A is supposed to be the original surface; B, C, D, E surfaces formed by corrosion, being constructed by circles having their centres on A. In B the ridges are still somewhat rounded, but they become sharp in D and E. The general tendency is to sharpen elevations and to smooth off depressions.

THE FUNCTIONS OF A UNIVERSITY.[1]

THE word University has borne many significations; and, indeed, its functions are various, and the signification attached to the word has depended on the particular point of view taken at the time. An eminent German, who visited me some years ago, made the remark after seeing University College:—"Aber, lieber Herr College, University College ist eine kleine Universität." So it is; for it fulfils most of the functions of the most successful Universities in the world. And why is this? Because the traditions of University College have always been, that it is not merely a place where known facts and theories should be administered in daily doses to young men and young women, but that the duties of the professors, assistant-professors, teachers and advanced students is to increase knowledge. That is the chief function of a University—to increase knowledge. But it is not the only one.

A University has always been regarded as a training school for the "learned professions," *i.e.* for theology, law and medicine. The terms of our charter have excluded the first of these branches of knowledge. Founded as it was in the '20's, when admission to Oxford or Cambridge involved either belief in the tenets of the Church of England or insincerity, it was not possible to provide courses in theology which should be acceptable to Nonconformists, Jews and others who desired education. On the whole, it appears to me better that a subject about which so much difference of opinion exists should be taught in a separate institution. There are many branches of knowledge which can be adequately discussed without intruding into any sphere of religious controversy; and, indeed, it would be difficult, I imagine, to treat mathematics or chemistry from a sectarian standpoint. I at least have never tried. There are subjects which may be placed on the border-line, for example, philosophy; but such subjects, and they are few in number, might well form part of the curriculum of the theological college, if thought desirable. It is a thousand pities that instead of founding King's College a theological college had not been established in the immediate neighbourhood of University College; it would have strengthened us, and it would have tended, too, to the advantage of the Church of England. However, what is done can't be undone; and let us wish all prosperity to our sister College, and a long and a useful life. We are now friends, and have been friends for many years. May that friendship long continue!

Dismissing the faculty of theology, therefore, as out of our power, as well as beyond our wishes, let us turn to the remaining two learned professions. University College, I believe, was the first place in England where a systematic legal education could be obtained. Our chairs of Roman law, constitutional law and jurisprudence were the first to be established in England, although such chairs had for long been known on the Continent, and in Scotland. "Imitation is the sincerest flattery," and in the fulness of time the Inns of Court started a school of their own. Our classes, which used to be crowded, dwindled, and our law-school is certainly not our strongest feature. I am not sufficiently acquainted with English legal education to pronounce an opinion as to whether methods of training as they at present exist in England are the most effective; I have heard rumours that they are not. That must be left to specialists to decide. But arguing from the experience of another faculty, in which the apprenticeship system once existed, and which has changed that system with a view to reform, and judging, too, from the experience abroad and in Scotland, I venture to think that some improvement in legal education is possible. If that opinion is correct, it is surely not too much to hope that the claims of University College may be considered as having made the first attempt to systematise legal education in England.

The faculty of medicine has existed in a flourishing state since the inception of University College. Not long after the College was built, the Hospital buildings, of which we have the last unsightly remains still before our eyes, were erected. One of my predecessors on a similar occasion to this has given you an entrancing account of the early history of this side of the College, and has discoursed on the eminent men who filled the chairs in the medical faculty. Here young men whose intention it is to enter the medical profession are trained; they now receive five years' instruction in the various branches of knowledge bearing on their important calling. I would point out that this function of a University is professedly a technical one—the training of medical men. True, many researches have been made by the eminent men who have held chairs in this faculty; but that is not the primary duty of such men; their duty is to train others to exercise a profession. If they advance their subject in doing so, so much the better; it increases the fame of the school, it imparts enthusiasm to their students, and in many cases their discoveries have been of unspeakable benefit to the human race. In a certain sense, every medical man is an investigator; the first essential is that he shall be able to make a correct diagnosis; the next, that he shall prescribe correct treatment. But novelty is not essential; few men evolve new surgical operations or introduce new remedies, and though we have in the past had not a few such, they are not essential for a successful medical school, the object of which is to train good practical working physicians and surgeons. The teaching staff of the medical faculty must of necessity be almost all engaged in practice, and, indeed, it would be unfortunate for their students if they were merely theoretical teachers. Let me again recapitulate my point; the medical faculty is essentially a technical faculty; the hospital is its workshop.

In England, of recent years, schools of engineering have been attached to the Universities. Abroad and in America they are separate establishments, and are sometimes attached to large engineering shops, where the pupils pursue their theoretical and practical studies together, taking the former in the morning, the latter in the afternoon. Here again the subject is a professional

[1] Oration delivered at University College, London, on June 6, by Prof. W. Ramsay, F.R.S.

one. The object of the student is to become a practical engineer, and all his work is necessarily directed to that end. Like other workers in different fields, his aim is the acquisition and utilisation of "power," but in his case it is his object to direct mechanical and electrical power so as to add to the convenience of the public. A machine is an instrument for converting heat or electrical energy into what is termed "kinetic energy," and it is with the laws and modes of this conversion that he has to deal. Such abstract sciences as chemistry, physics and geology, therefore, are studied as means to an end, not for their own sakes. They afford him a glimpse of the principles on which his engineering practice is based; and mathematics is essential in order that he may be able to apply physical principles to the practical problems of his profession.

We see, then, that a University, as it at present exists, provides, or may provide, technical instruction for theologians, for lawyers, for medical men and for engineers. It is, in fact, an advanced technical school for these subjects.

But it is more, and I believe that its chief function lies in the kind of work which I shall attempt now to describe. The German Universities possess what they term a "philosophical faculty"; and this phrase is to be accepted in the derivational meaning of the word—a faculty which befriends wisdom or learning. The watchword of the members of this faculty is research; the searching out the secrets of nature, to use a current phrase, or the attempt to create new knowledge. The whole machinery of the philosophical faculty is devised to achieve this end; the selection of the teachers, the equipment of the laboratories and libraries, the awarding of the degrees.

What are the advantages of research? Much is heard nowadays regarding the necessity of State-provision for its encouragement, and the Government places at the disposal of the Royal Society a sum of no less than 4000*l*. a year, which is distributed in the form of grants to applicants who are deemed suitable by committees appointed to consider their claims to assistance.

There are two views regarding the advantage of research which have been held. The first of these may be termed the utilitarian view. You all know the tale of the man of science who was asked the use of research and who parried with the question—What is the use of a baby? Well, I imagine that one school of political economists would oppose the practice of child-murder on the ground that potentially valuable property was being destroyed. These persons would probably not be those who stood to the baby in a parental relation. Nor are the most successful investigators those who pursue their inquiries with the hope of profit, but for the love of them. It is, however, a good thing, I believe, that the *profanum vulgus* should hold the view that research is remunerative to the public—as some forms of it undoubtedly are.

The second view may be termed the philosophical one. It is one held by lovers of wisdom in all its various forms. It explains itself, for the human race is differentiated from the lower animals by the desire which it has to know "why." You may have noticed, as I have, that one of the first words uttered by that profound philosopher, a small child, is "why." Indeed, it becomes wearisome by its iteration. We are the superiors of the brutes in that we can hand down our knowledge. It may be that some animals also seek for knowledge; but at best it is of use to themselves alone; they cannot transmit it to their posterity, except, possibly, by the way of hereditary faculties. We, on the contrary, can write and read; and this places us, if we like, in the possession of the accumulated wisdom of the ages.

Now the most important function, I hold, of a University is to attempt to answer that question, "why?" The ancients tried to do so; but they had not learned that its answer must be preceded by the answer to the question, "how?" and that in most cases—indeed in all—we must learn to be contented with the answer to "how?" The better we can tell *how* things are, the more nearly shall we be able to say *why* they are.

Such a question is applicable to all kinds of subjects; to what our forerunners on this earth did; how they lived; if we go even further back, what preceded them on the earth. The history of these inquiries is the function of geology, palæontology and palæontological botany; it is continued through archæology, Egyptian and Assyrian, Greek and Roman; it evolves into history, and lights are thrown on it by languages and philology; it dovetails with literature and economics. In all these, research is possible; and a University should be equipped for the successful prosecution of inquiries in all such branches.

Another class of inquiries relates to what we think and how we reason; and here we have philosophy and logic. A different branch of the same inquiry leads us to mathematics, which deals with spatial and numerical concepts of the human mind, geometry and algebra. By an easy transition we have the natural sciences; those less closely connected with ourselves as persons, but intimately related to our surroundings. Zoology and botany, anatomy, physiology and pathology deal with living organisms as structural machines, and they are based on physics and chemistry, which are themselves dependent on mathematics.

Such inquiries are worth making for their own sakes. They interest a large part of the human race, and not to feel interested in them is to lack intelligence. The man who is content to live from day to day, glad if each day will but produce him food to eat and a roof to sleep under, is but little removed from an uncivilised being. For the test of civilisation is *prevision*; care to look forward; to provide for to-morrow; the to-morrow of the race, as well as the to-morrow of the individual; and he who looks furthest ahead is best able to cope with nature, and to conquer her.

The investigation of the unknown is to gather experience from those who have lived before us, and to secure knowledge for ourselves and for those who will succeed us. I see, however, that I am insensibly taking a utilitarian view; I by no means wish to exclude it, but the chief purpose of research must be the acquisition of knowledge, and the second its utilisation.

I will try to explain why this is so, and here you must forgive me if I cite well-known and oft-quoted instances.

If attempts were made to discover only useful knowledge (and by useful I accept the vulgar definition of profitable, *i.e.* knowledge which can be directly transmitted into its money equivalent) these attempts would, in many, if not in most, cases fail of their object. I do not say that once a principle has been proved and a practical application is to be made of it that the working out of the details is not necessary. But that is best done by the practical man, be he the parson, the doctor, the engineer, the technical electrician or the chemist, and best of all on a fairly large scale. If, however, the practical end is always kept in view, the chances are that there will be no advance in principles. Indeed, what we investigators wish to be able to do, and what in many cases we can do, although perhaps very imperfectly, is to prophesy, to foretell what a given combination of circumstances will produce. The desire is founded on a belief in the uniformity of nature; on the conviction that what has been will again be, should the original conditions be reproduced. By studying the consequences of varying the conditions our knowledge is extended; indeed, it is sometimes possible to go so far as to predict what will happen under conditions, all of which have never before been seen to be present together.

When Faraday discovered the fact that when a magnet is made to approach a coil of wire an electric current is induced in that wire, he made a discovery which at the time was of only scientific interest. That discovery has resulted in electric light, electric traction and the utilisation of electricity as a motive power; the development of a means of transmitting energy, of which we have by no means seen the end; nay, we are even now only at its inception, so great must the advance in its utilisation ultimately become.

When Hofmann set Perkin as a young student to investigate the products of oxidation of the base aniline, produced by him from coal-tar, it would have been impossible to have predicted that one manufactory alone would possess nearly 400 large buildings and employ 5000 workmen, living in its own town of 25,000 inhabitants, all of which is devoted to the manufacture of colours from aniline and other coal-tar products. In this work alone at least 350 chemists are employed, most of whom have had a University training.

Schönbein, a Swiss schoolmaster interested in chemistry, was struck by the action of nitric acid on paper and cotton. He would have been astounded if he had been told that his experiments would have resulted in the employment of his nitro-celluloses in colossal quantity for blasting, and for ordnance of all kinds, from the 90-ton gun to the fowling-piece.

But discoveries such as these, which lead directly to practical results, are yet far inferior in importance to others in which a general principle is involved. Joule and Robert Mayer, who proved the equivalence of heat and work, have had far more influence on succeeding ages than even the discoverers above mentioned, for they have imbued a multitude of minds with a correct understanding of the nature of energy and the possibility of converting it economically into that form in which it is most directly useful for the purpose in view. They have laid the basis of reasoning for *machines;* and it is on machines, instruments for converting unavailable into available energy, that the prosperity of the human race depends.

You will see from these instances that it is in reality "philosophy" or a love of wisdom which, after all, is most to be sought after. Like virtue, it is its own reward; and as we all hope is the case with virtue too, it brings other rewards in its train, not, be it remarked, always to the philosopher, but to the race. Virtue, pursued with the direct object of gain, is a poor thing; indeed, it can hardly be termed virtue if it is dimmed by a motive. So philosophy, if followed after for profit, loses its meaning.

But I have omitted to mention another motive which makes for research; it is a love of pleasure. I can conceive no pleasure greater than that of the poet—the maker—who wreathes beautiful thoughts with beautiful words; but next to this I would place the pleasure of discovery, in whatever sphere it be made. It is a pleasure, not merely to the discoverer, but to all who can follow the train of his reasoning. And after all, the pleasure of the human race, or of the thinking portion of it, counts for a good deal in this life of ours.

To return. Attempts at research, guided by purely utilitarian motives, generally fail in their object, or at least are not likely to be so productive as research without ulterior motive. I am strengthened in this conclusion by the verdict of an eminent German who has himself put the principle into practice; who after following out a purely theoretical line of experiment, which at first appeared remote from profit, has been rewarded by its remunerative utilisation. He remarked, incidentally, that the professors in polytechnika—(what we should term technical colleges, intended to prepare young men for the profession of engineering and technical chemistry)—were less known for their influence on industry than University professors. The aim is different in the two cases; the polytechnika train men for a profession, the philosophical faculty of German Universities aims at imparting a love of knowledge; and, as a matter of fact, the latter *pay* in their influence on the prosperity of the nation better than the former. And this brings me to the fundamental theme of my oration. It is this:—That the best preparation for success in any calling is the training of the student in methods of research. This should be the goal to be clearly kept in view by all teachers in the philosophical faculties of Universities. They should teach with this object:—to awaken in their students a love of their subject and a consciousness that if he persevere, he, too, will be able to extend its bounds.

Of course, it is necessary for the student to learn, so far as is possible, what has already been done. I would not urge that a young man should not master, or at all events learn, a great deal of what has been already discovered before he attempts to soar on his own wings. But there is all the difference in the world between the point of view of the student who reads in order to qualify for an examination, or to gain a prize or a scholarship, and the student who reads because he knows that thus he will acquire knowledge which may be used as a basis of new knowledge. It is that spirit in which our Universities in England are so lamentably deficient; it is that spirit which has contributed to the success of the Teutonic nations, and which is beginning to influence the United States. For this condition of things our examinational system is largely to blame; originally started to cure the abuses of our Civil Service, it has eaten into the vitals of our educational system like a canker, and it is fostered by the further abuse of awarding scholarships as the results of examinations. The pauperisation of the richer classes is a crying evil; it must some day be cured. Let scholarships be awarded to those who need them, not to those whose fathers can well afford to pay for the education of their children. "Pot-hunting" and philosophy have absolutely nothing in common.

It follows that the teachers in the philosophical faculty should be selected only from those who are themselves contributing to the advancement of knowledge; for if they have not the spirit of research in them, how shall they instil it into others? It is our carelessness in this respect (I do not speak of University College, which has always been guided by these principles, but of our country as a whole) which has made us so backward as compared with some other nations. It is this which has made the vast majority of our statesmen so careless, because so ignorant, of the whole frame of mind of the philosopher, and which has made it possible for a man high in the political estimation of his countrymen to address on a recent occasion the remarks which he did to graduates of our University. It is true that one of the functions of a University is to "train men and women fit for the manifold requirements of the Empire;" that we should all heartily acknowledge; but no man who has any claim to University culture can possibly be contented if the University does not annually produce much work of research. It is its chief excuse for existence; a University which does not increase knowledge is no University; it may be a technical school, it may be an examining board, it may be a coaching establishment, but it has no claim to the name University. The best way of fitting young men for the manifold requirements of the Empire is to give them the power of advancing knowledge.

It may be said that many persons are incapable of exhibiting originality. I doubt it. There are many degrees of originality, as there are many degrees in rhyming, from the writer of doggerel to the poet, or many degrees of musical ear, from the man who knows two tunes, the tune of "God Save the King" and the *other* tune, to the accomplished musician. But in almost all cases, if caught young the human being can be trained, more or less, and, as a matter of fact, natural selection plays its part. Those young men and women who have no natural aptitude for such work—and they are usually known by the lack of interest which they take in it—do not come to the University. My experience is that the majority, or at least a fair percentage of those who do come, possess germs of the faculty of originating, germs capable of development, in many instances, to a very high degree. It is such persons who are of most value to the country; it is from them that advance in literature and in science is to be expected, and many of them will contribute to the commercial prosperity of the country. We hear much nowadays o. technical education; huge sums of money are being annually expended on the scrappy scientific education in evening classes of men who have passed a hard day in manual labour, men who lack the previous training necessary to enable them to profit by such instruction. It may be that it is desirable to provide such intellectual relaxation; I even grant that such means may gradually raise the intellectual level of the country; but the investment of money in promoting such schemes is not the one likely to bear the most immediate and remunerative fruit. The Universities should be the technical schools; for the man who has learned to investigate can bring his talents to bear on any subject brought under his notice, and it is on the advance, and not the mere dissemination, of knowledge that the prosperity of a country depends. To learn to investigate requires a long and hard apprenticeship; the power cannot be acquired by an odd hour spent now and again; it is as difficult to become a successful investigator as a successful barrister or doctor, and it requires at least as hard application and as long a period of study.

I do not believe that it is possible for young men or women to devote sufficient time during the evening to such work. Those who devote their evening hours to study and investigation do not bring fresh brains to bear on the subject; they are already fatigued by a long day's work; and, moreover, it is the custom in most of the colleges which have evening classes to insist upon their teachers doing a certain share of day work; they, too, are not in a fit state to direct the work of their pupils or to make suggestions as to the best method of carrying it out. Moreover, the official evening class is from 7 to 10 o'clock, and for investigation in science a spell of three hours at a time is barely sufficient to carry out successfully the end in view; indeed, an eight hours' day might profitably be lengthened into a twelve hours' day, as it not infrequently is. It is heartrending in the middle of some important experiment to be obliged to close and postpone it till a future occasion, when much of the work must necessarily be done over again.

These are some of the reasons why I doubt whether University education, in the philosophical faculty at least, can be successfully given by means of evening classes.

Although my work has lain almost entirely in the domain of science, I should be the last man not to do my best to encourage research in the sphere of what is generally called "arts." In Germany of recent years a kind of institution has sprung up which is termed a *Seminar*. The word may be translated a "literary laboratory." I will endeavour to give a short sketch on the way in which these literary laboratories are conducted. After the student has attended a course of lectures on the subjects to which he intends to devote himself and is ripe for research, he enters a Seminar, in which he is provided with a library, paper, pens and ink and a subject. The method of using the library is pointed out to him, and he is told to read books which bear on the particular subject in question; he is made to collate the information which he gains by reading, and to elaborate the subject which is given him. Naturally his first efforts must be crude, but "*c'est le premier pas qui coûte*." It probably costs him blame at the hands of his instructor; after a few unsuccessful efforts, however, if he has any talent for the particular investigation to which he has devoted himself, his efforts improve and at last he produces something respectable enough to merit publication. Thus he is exposed to the criticism of those best competent to judge, and he is launched in what may be a career in historical, literary or economic research.

Such a Seminar is carried on in philological and linguistic studies, in problems of economy involving statistics, in problems of law involving judicial decision, and of history in which the relations between the development of the various phases in the progress of nations is traced. The system is borrowed from the well-known plan of instruction in a physical or chemical laboratory. Experiments are made in literary style. These experiments are subjected to the criticism of the teacher, and thus the investigator is trained. But it may be objected that the youths who frequent our Universities have not a sufficient knowledge of facts connected with such subjects to be capable of at once entering on a training of this kind. That may be so; if it is the case, our schools must look to it that they provide sufficient training. Even under present circumstances, however, I do not think I am mistaken in supposing that a young man or woman who enters a University at the age of eighteen years with the intention of spending three years in literary or historical studies will not at the end of the second year be more benefited by a course at the Seminar, even though it should result in no permanent addition to literature or history, than if he were to spend his time in mere assimilation. It is not the act of gaining knowledge which profits, it is the power of using it, and while in order to use knowledge it is necessary to gain it, yet a training in the method of using knowledge is much more important and profitable than a training in the method of gaining it. I do not know whether there exists in this country a single example of the continental Seminar; there was some talk of founding such a literary laboratory in University College, but, as usual, the attempt was frustrated by a lack of funds; the attempt would also have been frustrated by the requirements of the present system of examination in the University of London; but there is, fortunately, good hope of changing that system and of developing the minds of students on those lines which have proved so fruitful where they have been systematically followed.

Many, I suppose, who are at present listening to me would be disappointed were I not to refer to the functions of a University with reference to examinations. A long course of training, lasting now for the best part of seventy years, has convinced the population of London that the chief function of a University is to examine. Believe me, the examination should play only a secondary part in the work of a University. It is necessary to test the acquirements of the students whom the teachers have under their charge, but the examination should play an entirely subordinate part. To aim at success in examinations is, unfortunately, too often the goal which the young student aims at, but it is one which all philosophical teachers deprecate. To infuse into his pupils a love of the subject which both are at the same time teaching and learning is the chief object of an enthusiastic teacher; there should be an atmosphere of the subject surrounding them—an umbra—perhaps I should call it an aura; for it should exert no depressing influence upon them. The object of both classes of students (for I count the teacher a student) should be to do their best to increase knowledge of the subject on which they are engaged. That this is possible many teachers can testify to by experience; and it is the chief lesson learned by a sojourn in a German laboratory. Where each student is himself engaged in research, interest is taken by the students in each others' work; numerous discussions are raised regarding each questionable point; and the combined intelligence of the whole laboratory is focussed on the elucidation of some difficult problem. There is nothing more painful to witness than a dull and decorous laboratory, where each student keeps to his own bench, does not communicate with his fellow-students, does not take an interest in their work and expects them to manifest no interest in his. It is only by friction that heat can be produced, and heat, by increasing the frequency of vibration, results, as we know, in light.

The student should look forward to his examination, not as a solemn ordeal which he is compelled to go through with the prospect of a degree should he be successful, but as a means of showing his teacher and his fellows how much he has profited by the work which he has done; those who pursue knowledge in this spirit and those, be it remarked, who examine in this spirit will look forward to examination with no apprehension; not, perhaps, with joy, for after all it is a bore to be examined and perhaps a still greater bore to examine, but it is a necessary step for the student in gaining self-assurance and the conviction of having profited by his exertions, and for the teacher as a means of ensuring that his instruction has not been profitless to his student. In this connection I cannot refrain from remarking that that genius for competition which has overridden our nation of England appears to me to be misplaced. Far too much is thought of the top man; very likely the second or even the tenth, or it may be the fiftieth, has a firmer grasp of his subject and in the long run would display more talent. Let us take comfort, however, in the thought that the day of examinations, for the sake of examinations, is approaching an end.

It may surprise many to learn that the suggestion that in England teachers do not usually examine their own pupils for degrees is, abroad, received in a spirit of surprise not unmixed with incredulity. Americans and Germans to whom I have mentioned this state of matters cannot realise that the teacher is not considered fit to be trusted to examine his own pupils, and, singular to state, they maintain that no one else can possibly do so with any attempt at fairness; it appears to them, as it appears to me, an altogether untenable position to hold that a man selected to fill an important professorship, after many years' trial in a junior position, should be suspected of such (shall I say) ambiguous ideas regarding common honesty that he will always arbitrate unfairly in favour of his own pupils. Such a supposition is an insult to the professor, and the exclusion of the teacher elevates examination to the position of a fetish; it is that, together with the spirit of emulation and competition, which has done so much to ruin our English education. The idea of competitive examination is so ingrained in the minds of Englishmen that it is difficult for them to realise that the object of a University is, not primarily to examine its pupils, but to teach them to teach themselves; and also they have still to acquire the conviction that students should be found, not merely among the *alumni* of the University, but also among all members of the staff. The spirit which should prevail with us should be the spirit of gaining knowledge—gaining knowledge, not for the satisfaction of one's own sense of acquisitiveness, but in order to be able to increase the sum total of what is known. All should work together, senior and junior staff, graduates and undergraduates, in order to diminish man's ignorance.

To sum up. As it exists at present, a University is a technical school for theology, law, medicine and engineering. It ought to be also a place for the advancement of knowledge, for the training of philosophers, of those who love wisdom for its own sake; and while as a technical school it exercises a useful function in preparing many men and women for their calling in life, its philosophical faculty should impart to those who enter its halls that faculty of increasing knowledge which cannot fail to be profitable, not only to the intellect of the nation, but also to its industrial prosperity. I regard this as the chief function of a University.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE doctorates conferred by American Universities during the academic year lately concluded, and the subjects of the theses presented, are summarised in *Science* of August 2. The degree of doctor of philosophy was conferred on 253 candidates—a number which is probably greater than that of any previous year. Of these degrees 122 were given for subjects belonging to the humanities, and 131 for science subjects. Harvard and Yale have this year given as many degrees in the sciences as in the humanities, whereas in previous years the humanities have predominated, as the sciences have at Johns Hopkins and Cornell. There was a relative excess in the number of degrees in chemistry at Johns Hopkins; in physics at Cornell and Johns Hopkins; in mathematics at Yale; in zoology at Chicago; in psychology at Clark, Yale and Harvard, and in geology at Johns Hopkins and Harvard. Taking all the Universities together, the six subjects in which the most doctorates were conferred are:—chemistry, 28; physics, 23; mathematics, 18; zoology, 15; psychology, 13; geology, 10. The remaining 24 degrees were divided among twelve sciences.

SPECIAL courses of evening lectures for teachers and advanced students have been arranged by the London Technical Education Board at University College, King's College and Bedford College. The courses of instruction will afford an opportunity to students who can study only in the evenings to obtain instruction in well-equipped laboratories, and will make available to evening students the same advantages as are enjoyed by University day students, but they are only intended for those who are practically engaged during the day in some trade, business or occupation. At University College, Prof. J. A. Fleming, F.R.S., will give a course of ten lectures, followed by laboratory demonstrations, on advanced electrical measurements. Prof. Carus Wilson will give a course of lectures on the electric motor, with special reference to its employment in electric tram-car traction. In connection with these two courses, a special course of about twenty lectures on alternating currents will be given at King's College by Prof. E. Wilson, followed by a class for practical work. Prof. D. S. Capper will give about twenty lectures upon steam and gas engines, accompanied by laboratory work, and Prof. J. D. Cormack will lecture upon properties and testing of materials of construction. A course of civil engineering will also be given by Prof. Robinson. A course of twelve lectures on the recent developments of chemical theory will be given, under the direction of Prof. Ramsay, at University College, and a course of eight lectures dealing with the methods of spectroscopy, especially in connection with the photography of the spectrum, will be given by Mr. E. C. C. Baly. Saturday morning courses have been arranged for teachers; they include lectures on the teaching of mathematics, by Prof. Hudson, F.R.S.; physics, by Prof. W. Grylls Adams, F.R.S., and Mr. S. A. F. White; practical physiology, by Prof. Halliburton, F.R.S.; and a course on the teaching of elementary chemistry, by Mr. H. Crompton, at Bedford College.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 5.—M. Fouqué in the chair.—On Poisson's theorem and on a recent theorem of M. Buhl, by M. Paul Appell. The theorem of Buhl is a particular case of Poisson's theorem.—The law of pressures in cannon, by M. Vallier.—New method of preparing aniline and its analogues, by MM. Paul Sabatier and J. B. Senderens. A mixture of hydrogen and nitrobenzene vapour is passed over reduced copper kept at a temperature of from 300°-400° C., the yield of aniline being nearly theoretical. If nickel is employed instead of the copper, the reaction goes farther even at 200°, benzene and ammonia being produced.—On the luminous variation of the planet Eros; curves of light; amplitude of the variation, by M. Ch. André.—On the infinitely small deformation of a spherical elastic envelope, by MM. Eugène and Francois Cosserat.—On a relation which probably exists between the characteristic angle of deformation of metals and the Newtonian coefficient of restitution, by M. G. Gravaris. The characteristic angle of deformation (a), and the Newtonian constant of restitution (e), appear to be related according to the equation $\pi e = 2a$.—Critical study of the general theory of mechanisms, by M. G. Kœnigs.—On disruptive discharge in electrolytes, by M. K. R. Johnson.—Remarks on a communication of MM. A. Broca and Turchini.—The electric capacity of the human body, by M. G. de Metz. It follows from the experiments described that it is illusory to compare the electric capacity of the human body with that of an ellipsoidal conductor. The same person may possess several capacities according to the conditions under which he is placed. The average figure found is about 0·00011 microfarad.—The difference of potential and the deadening of the electric spark with oscillatory character, by M. F. Beaulard.—On the transmission of Hertzian waves through conducting liquids, by M. Charles Nordmann. For the liquids studied (solutions of sulphuric acid, common salt, potassium chloride and magnesium sulphate), the maximum thickness which could be traversed by the waves employed, that is to say, the transparencies for the waves, varies in the same sense as the resistances, but not in proportion.—The vapour tension of solutions. The hypothesis of Arrhenius, by M. A. Ponsot.—An attempt at an immediate analysis of nervous tissue, by M. N. Alberto Barbieri.—On the cycloplasmic maturation, by M. Yves Delage.—Carboniferous goniatites in the Sahara, by M. Collot. The discovery of goniatites in the carboniferous layers of the Sahara points to an age a little more recent than that deduced by M. Ficheur, and it shows further that there were several levels, amongst which that which furnished the goniatites may be contemporaneous with the layers observed by Foureau in the Tassli Adzjer.—A physiological photometer, by M. G. M. Stanoiévitch.

JAPANESE SPONGES.

Studies on the Hexactinellida. Contribution I. (Euplectellidæ). By Isao Iijima. Pp. 299; 14 plates. (Reprinted from the *Journal of the College of Science*, Imperial University, Tōkyō, Japan, vol. xv. 1901.)

THIS important memoir is the first instalment of a general monograph of the rich Hexactinellid fauna of the Japanese seas, upon the study of which the author has been engaged for the last seven years, with the result of increasing very largely the list of these interesting and beautiful sponges known to occur in that part of the world. Four species of *Euplectella*, three of *Regadrella* and one of *Walteria* are here described in great detail, and all but two of them are species described and named by the author himself, either in previous publications or in this memoir for the first time. The part of the work, however, which above all claims the attention of the zoologist who is not specially interested in this group of animals, or in the faunistic problems which attach to them, is the detailed account of the histology and organisation of *Euplectella marshalli* (pp. 116–200). The author has had at his disposal a very abundant material of this sponge, which he was able to preserve by various methods directly after capture. As the result of his careful studies upon this valuable material, the author describes in these Hexactinellids a type of structure which is radically different in two main points from that of all other sponges, and in both respects probably to be regarded as more primitive.

In the first place, he finds no trace of the intercellular matrix or mesoglœa of the connective tissue parenchyma, which in other sponges forms the chief mass of the sponge body. In the second place, perhaps in consequence of the absence of any such ground substance, there is no layer of flat epithelium to be found on any part of the sponge body, neither on the external surface nor in the canal system.

The dermal layer, in short, forms in these Hexactinellids a system of trabeculæ, composed of fused cells corresponding to the collencytes of other sponges, which here form a continuous protoplasmic syncytium with scattered nuclei. In this syncytium the spicules are laid down, but there is no secreted matrix apart from them and from the protoplasm of the syncytium, nor is there any flat epithelium covering the exposed surfaces. The trabeculæ anastomose and form a cobweb-like felt-work, through which the water filters both before and after traversing the flagellated chambers. At the external and internal surfaces of the body wall the trabeculæ are expanded to form film-like membranes perforated by numerous gaps or pores, the so-called dermal and gastral membranes. In the trabecular system are found other cellular elements, the archæocytes, with their modifications into nutritive and reproductive elements.

If the author's observations are confirmed, therefore, the Hexactinellids stand on a lower plane of evolution, at least as regards histological structure, than any other sponges, in that the dermal layer forms only one category of cell elements and is not differentiated into separate epithelial and connective tissue strata. This conclusion, it is hardly necessary to point out, is in direct antagonism to the view, still maintained by many authorities, according to which these two commonly found differentiations of the dermal layer are to be regarded as an "ectoderm" and a "mesoderm" respectively. In the author's words, the Hexactinellids "are a group of sponges which have undergone a far-reaching development and differentiation in the spicules, but have remained in a primitive condition so far as certain points in the soft parts are concerned."

The author has also made a number of important observations upon other points of microscopic structure. He brings forward the first observations yet made upon the formation of spicules in these sponges. He has also observed "archæocyte congeries" which he believes to give rise to free larvæ, thus reverting to, and supporting, the view of H. V. Wilson, that many sponge larvæ are really free-swimming gemmules, and are not egg-larvæ. But the account given of the collar cells and flagellated chambers merits special mention, as differing in some points, both important and unimportant, from Schulze's recently published description of the collar cells in another Hexactinellid, *Schaudinnia arctica.* Each collar cell has a flattened basal portion containing the nucleus and running out into ramifying processes, which anastomose with those of neighbouring cells to form the "reticular membrane" of Schulze. According to Iijima, all the meshes of the reticular membrane are open and serve as prosopyles or chamber pores, which are therefore practically equal in number to the collar cells themselves, "converting the epithelium into a veritable sieve membrane." The trabeculæ of the dermal layer attach themselves directly to the reticular membrane. The "polyprosopylar" condition here described contrasts sharply with what is seen in other sponges, and in the author's opinion it is correlated with the absence of mesoglœa. In sponges other than Hexactinellids, *i.e.* in Calcarea and Demospongiæ, the copious deposit of the ground substance round the bases of the collar cells necessarily blocks the free infiltration of the water between them, and causes a specialisation of the prosopyles; they become few in number and restricted in distribution, while between them the collar cells close up their ranks and extinguish the gaps in the wall. In Calcarea at least, it may be added, the prosopyles are further guarded, each by a special cell or porocyte of the dermal layer. These porocytes have not as yet, however, been demonstrated to occur in Demospongiæ, and their existence in Calcarea is, perhaps, a peculiarity of this group alone.

The histological facts brought forward by the author throw a flood of light upon the nature of the prosopyles or primitive pores of sponges, and if carried back in imagination to the primitive vase-like Olynthus form, which was probably the ancestor of all sponges, they permit of interesting speculations as to the probable structure of the body wall in such a form. The earliest type of sponge must be pictured as entirely without mesoglœa, and with a thin basket-like wall perforated by very numerous pores or interstices, corresponding to the intervals between the collar cells. The first advance towards strengthening this fragile structure would have been the secretion of spicules, formed by cells, probably at first very few in number, of the dermal layer, which continually increased in numbers and in importance, not only for the better support and protection of the sponge body and in particular of the reproductive cells, but also, perhaps, for entangling and capturing the nutritive particles brought by the water current. Clearly, so delicate an organism could only maintain its existence in tranquil water. The ancestors of the Calcarea and Demospongiæ, by the development of a thick and often very tough mesoglœa and a highly differentiated dermal layer, attained to the degree of firmness necessary for life in the littoral zone. The Hexactinellids, with a more primitive type of histological structure, have retained also their ancient deep-sea habitat.

Enough has been said to show the important results of Prof. Iijima's researches. We may add that the plates accompanying the work are a credit, not only to the author, but also to Japanese lithography. We shall await further instalments with much interest. E. A. MINCHIN.

INSTRUCTION IN VILLAGE SCHOOLS.

Rural Readers. Book I. By Vincent T. Murché. Pp. 168. (London: Macmillan and Co., Ltd., 1901.)

The Teacher's Manual of Object Lessons for Rural Schools. Books I. and II. By the same author. Pp. 231 and 252.

THESE books have been written by the headmaster of the Boundary Lane Board School, Camberwell, to meet the requirements of teachers in rural schools as laid down in the suggestive circular recently issued by the Board of Education. Mr. Murché claims to be an old hand at rural education, and the books before us certainly bear out his claim. If properly used, teachers will find them most valuable guides in introducing nature study into elementary schools. Their value is so much dependent on their mode of use that the author's caution, as given in the preface, must be kept well in mind. He says,

> "*These books are not intended to form a rigid cast-iron scheme of lessons*, to be blindly followed by every teacher into whose hands they may fall. They are rather to be considered as *a store-house from which the teacher may draw*, to suit his own special conditions; and further, the ample provision of subjects in each volume will enable him for years to construct scheme after scheme, all of them dealing with *just those subjects which will appeal to country children.*"

A brief summary of the contents will enable our readers to form an idea of the ground covered. Book I. (Object Lessons) contains forty lessons, grouped under six headings; lessons from simple natural phenomena such as the air, the sky, the sun, clouds and rain, wind and weather, &c.; round about the farm; lessons on the seasons; animals kept on the farm; and some useful minerals. Book II. contains forty lessons, grouped under lessons from animals, domestic and wild; lessons from birds; lessons from plants, and a number of miscellaneous lessons. The "Reader," of which the first part only is at present before us, is arranged in dialogue form and is to be used in conjunction with the corresponding volume of object lessons. We have nothing but praise for Mr. Murché's little books. They are the best of the kind that have hitherto come under our notice, and should go a long way towards facilitating that kind of teaching which all those who have taken part in the modern revival in rural education have been so anxious to see introduced into village schools. The great danger attending the use of such books is of course the tendency shown by teachers to make a fetish of the printed page. It is so much easier to teach didactically and to pump information into pupils from printed books than it is to develop their individual powers of observation and reasoning that extreme advocates of the "heuristic" method might take exception to the present volumes, as calculated to play too much into the hands of the teacher and to leave too little to the pupils themselves. But this danger is not confined particularly to rural education; it lurks in the pages of teachers' manuals in every branch of science, and if the publication of such works has injured the cause of true education it is more frequently the teachers than the authors who are at fault.

With respect to rural education in particular, it must not be forgotten that it has lagged far behind the education in towns, and that now—largely owing to the work of the Agricultural Education Committee—it is in a state of transition. The practical difficulties in the way of rational teaching in village schools are familiar to all who have attempted to grapple with the problem. Not the least of these difficulties is the imperfect education of the teachers themselves. Some of the technical instruction committees, as in Essex, have done good work through their normal classes, but much remains to be done before a body of teachers thoroughly trained in the requirements and in full sympathy with the objects of rural education can be called into existence. There are teachers in many such schools who are anxious to meet the new conditions now made possible through the enlightened policy of the Board of Education if they are helped in the way that Mr. Murché has attempted to help them by showing what there is to teach and how to teach it. If conducted rationally and scientifically, these object lessons will certainly accomplish the purpose for which they are written.

There is one little side issue to which the writer of this notice is glad of the present opportunity of calling attention. Now that the education of country children is making a serious departure in the right direction, the time seems ripe for inculcating that respect for living nature which is generally absent in the average child. Boys and girls are naturally destructive animals. The teachers in rural schools can do more than any other class of people to restrain and direct this tendency. They have to deal with children at the most impressionable period of their lives, and they have it in their power to point out exactly why wanton destruction is to be deprecated. The collecting of the common forms of animal and vegetable life for the purposes of study, *i.e.* for educational purposes, might be encouraged *judiciously*, but the ruthless destruction that accompanies the ordinary country ramble should be severely censured. If hordes of village school children are to be taken out into the country without proper restraint, the "nature study" is apt to degenerate into a mere collecting raid with no educational value and with serious consequences to our native fauna and flora. The teachers have it in their hands to impress upon their pupils that nothing is to be gained and everything to be lost by plucking every flower because it looks pretty, by raiding every nest because it is good sport, or by killing every insect that looks strange. If by proper tuition the child can be made to realise how infinitely more instructive and interesting is the living organism than the dead "specimen," a well-organised course of nature study should have as distinct a moral influence as it is intended to have an intellectual influence in moulding the character of the pupil. For this reason we should like to see in such works as those under consideration special and emphatic recommendations to teachers to repress all unscientific collecting. R. MELDOLA.

HEDDLE'S MINERALOGY.

The Mineralogy of Scotland. By the late M. Forster Heddle, M.D., F.R.S.E., Emeritus Professor of Chemistry, St. Andrews. Edited by J. G. Goodchild, H.M. Geological Survey, F.G.S. Two vols. Pp. 148 and 212. (Edinburgh: David Douglas, 1901.)

NO book is of more use to the practical mineralogist and collector than one which describes in a detailed manner the mineral localities of a country. Among the best examples are the lexicon of Zepharovich and Becke for Austria; that of Frenzel for Saxony; and, on a much more elaborate scale, the treatise by Lacroix on the mineralogy of France and her colonies, which is still in progress.

Greg and Lettsom's "Mineralogy of Great Britain and Ireland" (1858) is also a very useful book of reference, but scarcely adequate at the present date. Much of that work was actually due to Prof. Heddle; and it was known that he was for many years collecting materials for a "Mineralogy of Scotland"; no man possessed anything like his intimate knowledge of Scotch localities, so that a treatise of considerable importance and magnitude was expected from him.

After his death the unfinished manuscript was left to Mr. Alexander Thoms, who placed the work of completion in the competent hands of Mr. J. G. Goodchild. The present handsome volumes are the result, and it is evident that no trouble has been spared in their production. The book is a worthy monument of Prof. Heddle's lifelong labours, and will rank with the above-mentioned treatise of Lacroix.

Mr. Goodchild's task must have been a heavy one. There was a great mass of detail to be sifted; many of the localities have been difficult to identify, having been phonetically spelt by the author in his early journeys and not existing in the maps; further, it is not known to what specimens many of the figures relate, or what is the meaning of their symbols.

Prof. Heddle was an expert draughtsman, and there are no less than 103 plates, each containing about eight figures beautifully drawn and engraved. But many of these are taken from other sources, and their origin is doubtful. Confronted with the impossibility of making a trustworthy selection, the editor has thought it best to publish all the figures, though many of them have, perhaps, little direct bearing on the mineralogy of Scotland. These figures, and the numerous chemical analyses quoted throughout the book bear witness to Prof. Heddle's untiring industry.

In addition to these plates, a remarkable feature of the book is a number of beautiful and elaborate stereographic and gnomonic projections drawn by Mr. Wilbert Goodchild. The only book which has hitherto been provided with such complete stereographic projections is Des-Cloizeaux's "Manuel de Minéralogie," and even they are not so elaborate as those which adorn the present book. The gnomonic projections are quite a new feature, and will probably be found useful. The book is, further, provided with very complete tables and indices of mineral names, localities, pseudomorphs, &c.

A great part of such a book as this must necessarily consist of a mere list of localities; but, in addition, an account of the crystalline forms and of the physical and chemical properties is given for each mineral, and under some species will be found a good deal of interesting comment and historical information—conspicuous examples are gold, silver, galena and niccolite.

The reader's attention may be particularly directed to the description of agate and onyx, where he will find a very interesting and suggestive account of their probable mode of formation.

The most important part of the book is the description of the mineral localities; errors in the other portions are not of so much account, but it may be noted that it is not correct to call the form x of quartz a double three-sided pyramid, nor the face a the twin plane of pyrites.

The term gleit-face is a curiously hybrid expression for the glide-plane (*Gleitebene*) of calcite, and some of the terms used in the description of the varieties of agate, such as Jasp-agate, Oonachatæ, Hæmachatæ, Hæma-ovoid agate, can scarcely be regarded as satisfactory.

One failing inseparable from a posthumous work of this character may be noted; the reader, not knowing how much is generally established fact, and how much derived from incomplete or inadequate notes of the author, cannot feel equal confidence in all the statements. It is difficult, for example, to feel entire confidence in the occurrences of some obscure minerals, or in the identification of many of the crystal forms. It would have been well if Mr. Goodchild could have distinguished in some way those statements which he has been able to confirm from his personal knowledge and from his own extensive experience or from that of others. An appendix which contains some of his own observations is for this reason particularly valuable.

The book, as a whole, is remarkably free from the ornate style and the tinge of romance displayed by many of Prof. Heddle's published papers. It must long remain the standard treatise on the mineralogy of Scotland. It is satisfactory to know that the author's extensive collection of Scotch minerals is in the Museum of Science and Art at Edinburgh, and has been carefully arranged and made intelligible to the public by Mr. Goodchild, to whom the hearty thanks of all mineralogists are due for the labour and care which he has bestowed both upon the collection and upon the present treatise.

H. A. MIERS.

THE CIRCULATION OF THE ATMOSPHERE.

Mémoires originaux sur la Circulation générale de l'Atmosphere. Annotés et Commentés par Marcel Brillouin, Maître de Conférences à l'École Normale Supérieure. Pp. xx + 163. (Paris: Georges Carré et C. Naud, 1900.)

THIS may be described as a French Student's note-book of foreign memoirs upon the general circulation of the atmosphere. It contains papers upon the subject, partly translated in full, partly in extract or analysis, by Halley, Hadley, Maury, Ferrel, James Thomson, W. von Siemens, Möller, Oberbeck and von Helmholtz, with a short introduction and some critical notes to the current text.

The book may be welcomed as calling attention to a subject which greatly needs attention in this country. But little has been done for it since James Thomson, in the Bakerian lecture of 1892, revived the ideas he had originally put forward at the meeting of the British Association at Dublin in 1857. In the United States Prof. Cleveland Abbé has collected and translated the principal memoirs, but the mathematical treatment of atmospheric circulation has been neglected in England.

Contrary to the general experience of scientific books in French, the work is rather dull. The introduction makes it clear that only foreign memoirs are included, and the work of MM. Tastes and Duclaux, as well as that of M. Teisserenc de Bort and of M. Brillouin himself, particularly "Vents contigus et nuages" (*Ann. du Bur. Centr. Mét.* 1898) is only incidentally referred to, but this does not altogether account for the impression. The subject itself is difficult; indeed, in its details it is far beyond the power of mathematics. No one can suppose that it is possible to deduce the actual motion of the air at this instant at every part of the globe from its primary causes, namely the insolation of one half the globe, the radiation from the other half, the force of gravity and the rotation of the earth; and yet that is what, in a generalised manner, most of the authors quoted set out to do. Of course, a conventional atmosphere has to be used and a conventional circulation therein accounted for; and, as a matter of fact, the assumptions and conventions that a writer makes in order to bring his powers of calculation to bear are more interesting than the details of elaborate mathematics on artificial hypotheses leading to results which, to put the matter bluntly, are only true in so far as they are not new.

Von Siemens' application of the principles of conservation of momentum and of energy strikes a livelier key, but it is only when von Helmholtz's papers are reached that the reader can feel that the analysis has really become an engine of research. The mode of treatment becomes quite different. The hydrodynamics and thermodynamics of real air are the starting point, and equatorial heating becomes a secondary consideration. As each section is developed, and the dynamical effect of the scale of the problem, the equilibrium shapes of atmospheric layers, the wave phenomena that can occur between layers of different density are unfolded, it becomes possible to be enthusiastic as to the service that mathematics can render to this subject.

Von Helmholtz himself gives no general system of atmospheric circulation, but M. Brillouin indicates the results in that direction that flow from his conclusions. He finds them in general agreement with Ferrel's distribution, and pays a tribute to Ferrel's achievement on that account.

The notes throughout are frank, appropriate and useful. It is to be feared that the book appeals to a limited class of readers, namely those who are at the same time meteorologists and mathematicians. The ordinary meteorologist will feel the want of a mathematical introduction, and the ordinary mathematician of a meteorological introduction.

W. N. S.

OUR BOOK SHELF.

The Elements of the Differential and Integral Calculus. By J. W. A. Young, Assistant Professor of Mathematical Pedagogy in the University of Chicago, and C. E. Linebarger, Instructor in Chemistry and Physics in the Lake View High School, Chicago. Pp. xvii + 410. (London: Hirschfeld Bros., 1900.) Price 10*s*. 6*d*. net.

Differential and Integral Calculus with Applications for Colleges, Universities, and Technical Schools. By E. W. Nichols, Professor of Mathematics in the Virginia Military Institute. Pp. xi + 394. (Boston, U.S.A.: D. C. Heath and Co., 1900.)

THE first of these books is based upon the German treatise on the differential and integral calculus with special reference to chemistry which was published by Profs. Nernst and Schönflies five or six years ago. The chief alteration in the mode of presenting the subject is that the method of limits is used throughout in the treatise before us to the exclusion of the method of differentials which was early introduced and much employed in the German text-book. But the distinctive feature of the original work, viz. the continual use of illustrative examples from chemical and physical science, has been retained in the adaptation before us, and many additional examples of the like kind have been introduced.

The treatise in its present shape forms a very convenient and serviceable text-book for English and American students of chemistry desirous of obtaining an elementary acquaintance with the principles and methods of the calculus, for here they will find a very clear presentation of the fundamental ideas of the subject, and in particular will be furnished with abundant easy exercises and applications of the mathematical processes to subjects in which they are specially interested. The book is well designed to save the time and keep up the interest of such students. Thus the first chapter contains an introduction to analytic geometry, with numerous exercises on the graphing of curves, and the last chapter is a characteristic one on the differentiation and integration of functions found empirically.

Whilst so much has been done to smooth the path and provide for the wants of the class of students specially in view, it seems matter for regret that an additional chapter on the solution of easy linear differential equations has not been furnished.

We have in Prof. Nichols' work another elementary text-book specially designed as a first book on the calculus for students of physics and engineering. It is a clear and teachable work for beginners, and contains several easy applications to mechanics and electricity. The ordinary applications of the differential calculus to geometry are brought forward earlier than usual; thus we have a chapter on tangents, normals and asymptotes to plane curves before the chapters on successive differentiation, series, illusory forms and maxima and minima. Then, after a chapter on partial and total differentiation, we have applications to curvature, envelopes, singular points and tracing of curves.

The second part of the book contains the fundamental methods of the integral calculus, including a slight treatment of double and triple integrals and their applications to surfaces and volumes.

There is also a short chapter on differential equations, giving the methods of dealing with some of the simpler forms, and the concluding chapter contains applications to such subjects as moments of inertia and the deflection of beams.

Compared with recent English treatises on the calculus for engineering and physical students, the work before us appears slight and superficial in its technical applications. But as an elementary text-book on pure mathematics it has decided merit, and is evidently the production of an experienced teacher.

Album de Aves Amazonicas. Organisado pelo Dr. Emilio A. Goeldi, Director do Museu Paraense. (Museu Paraense de Historia Natural e Ethnographia, 1900.)

THE illustrated supplement to Dr. Goeldi's "Aves do Brazil," of which the first part, consisting of twelve coloured plates designed by Señor Ernesto Lohse, has been issued, will when completed give a good general idea of the avifauna of those regions. The birds represented in the present fasciculus comprise the cormorants, grebes, gulls, terns, waders, plovers, herons, egrets, boatbill, storks, spoonbills, rails, geese, ducks, toucans and kingfishers, as well as those two curious forms, the hoactzin and the sun-bittern. In herons and their allies the country is very rich, and two plates illustrate ten species of toucan, both sexes in this, as well as in other cases, being figured when desirable. Several species are figured on most of the plates, and they number eighty in all. But one plate is entirely devoted to a beautiful illustration (produced from an instantaneous photograph taken in 1900) of a breeding-place of the scarlet ibis. The crowd of graceful scarlet birds, backed by the rich, deep greenery of the western tropics, must afford a sight worth going to South America to see. There are pleasing bits of tropical scenery in the background of the plates, which form quite pretty pictures. The work has been printed at Zürich, and although the designs are on a rather small scale, and too much must not be expected of colour-printing, the illustrations of the birds strike us as being decidedly good, and we readily recognise at a glance several old South American acquaintances. The supplement will be most useful to any one travelling in the country who takes even a passing interest in natural history. The plates, like Dr. Goeldi's recently completed "Aves do Brazil," may be regarded as decidedly popular, and on that account will doubtless prove the more generally useful.

Qualitative Chemical Analysis, Organic and Inorganic. By F. Mollwo Perkin, Ph.D. Pp. viii + 266. (London: Longmans, Green and Co., 1901.)

THIS book begins with a general account of dry reactions and reactions in solution, attention being paid both to the manipulative and the theoretical aspects. Then follows the usual account of metals in groups with their tests, and afterwards come the acids. The remaining third of the book is devoted to what is called organic analysis, and here appears the most distinctive feature, namely, a list of tests for a great variety of organic substances—acids, alcohols, sugars, nitrogenous bases, glucosides and alkaloids. The intention of the author, as declared in the preface, has been "to write a book in which theory and practice are more or less dovetailed." It is difficult to find any realisation of this in the large section devoted to organic substances, but the treatment of the inorganic section is more in accordance with the stated object. A. S.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Fire Walk Ceremony in Tahiti.

THE very remarkable description of the "Fire Walk" collected by Mr. Andrew Lang and others had aroused a curiosity in me to witness the original ceremony, which I have lately been able to gratify in a visit to Tahiti.

Among these notable accounts is one by Colonel Gudgeon, British Resident at Raratonga, describing the experiment by a man from Raiatea, and also a like account of the Fiji fire ceremony from Dr. T. M. Hocken, whose article is also quoted in Mr. Lang's paper on the "Fire Walk," in the *Proceedings* of the Society for Psychical Research, February, 1900. This extraordinary rite is also described by Mr. Fraser in the "Golden Bough," and by others.

I had heard that it was performed in Tahiti in 1897, and several persons there assured me of their having seen it, and one of them of his having walked through the fire himself under the guidance of the priest, Papa-Ita, who is said to be one of the last remnants of a certain order of the priesthood of Raiatea, and who had also performed the rite at the island of Hawaii some time in the present year, of which circumstantial newspaper accounts were given, agreeing in all essential particulars with those in the accounts already cited. According to these, a pit was dug in which large stones were heated *red hot* by a fire which had been burning many hours. The upper stones were pushed away just before the ceremony, so as to leave the lower stones to tread upon, and over these, "glowing red hot" (according to the newspaper accounts), Papa-Ita had walked with naked feet, exciting such enthusiasm that he was treated with great consideration by the whites, and by the natives as a God. I found it commonly believed in Tahiti that anyone who chose to walk after him, European or native, could do so in safety, secure in the magic which he exercises, if his instructions were exactly followed. Here in Tahiti, where he had "walked" four years before, it was generally believed among the natives, and even among the Europeans present who had seen the ceremony, that if anyone turned around to look back he immediately was burned, and I was told that all those who followed him through the fire were expected not to turn until they had reached the other side in safety, when he again entered the fire and led them back by the path by which he had come. I was further told by several who had tried it that the heat was not felt upon the feet, and that when shoes were worn the soles were not burned (for those who followed the priest's directions), but it was added by all that much heat was felt about the head.

Such absolutely extraordinary accounts of the performance had been given to me by respectable eyewitnesses and sharers in the trial, confirming those given in Hawaii, and, in the main, the cases cited by Mr. Lang, that I could not doubt that if all these were verified by my own observation, it would mean nothing less to me than a departure from the customary order of Nature, and something very well worth seeing indeed.

I was glad, therefore, to meet personally the priest, Papa-Ita. He is the finest looking native that I have seen; tall, dignified in bearing, with unusually intelligent features. I learned from him that he would perform the ceremony on Wednesday, July 17, the day before the sailing of our ship. I was ready to provide the cost of the fire, if he could not obtain it otherwise, but this proved to be unnecessary.

Papa-Ita himself spoke no English, and I conversed with him briefly through an interpreter. He said that he walked over the hot stones without danger by virtue of spells which he was able to utter and by the aid of a goddess (or devil as my interpreter had it), who was formerly a native of the islands. The spells, he said, were something which he could teach another. I was told by others that there was a still older priest in the Island of Raiatea, whose disciple he was, although he had pupils of his own, and that he could "send his spirit" to Raiatea to secure the permission of his senior priest if necessary.

In answer to my inquiry as to what preparations he was going to make for the rite in the two or three days before it, he said he was going to pass them in prayer.

The place selected for the ceremony fortunately was not far from the ship. I went there at noon and found that a large shallow pit or trench had been dug, about nine feet by twenty-one feet and about two feet deep. Lying near by was a pile containing some cords of rough wood and a pile of rounded water-worn stones, weighing, I should think, from forty to eighty pounds apiece. They were, perhaps, 200 in number, and all of porous basalt, a feature the importance of which will be seen later. The wood was placed in the trench, the fire was lighted and the stones heaped on it, as I was told, directly after I left, or at about twelve o'clock.

At 4.0 p.m. I went over again and found the preparations very nearly complete. The fire had been burning for nearly four hours. The outer stones touched the ground only at the edges of the pile, where they did not burn my hand, but as they approached the centre the stones were heaped up into a mound three or four layers deep, at which point the lowest layers seen between the upper ones were visibly red-hot. That these latter were nevertheless sending out considerable heat there could be no question, though the topmost stones were certainly not red-hot, while those at the bottom were visibly so and were occasionally splitting with loud reports, while the flames from the burned wood near the centre of the pile passed up in visible lambent tongues, both circumstances contributing to the effect upon the excited bystanders.

The upper stones, I repeat, even where the topmost were presently removed, did not show any glow to the eye, but were unquestionably very hot and certainly looked unsafe for naked feet. Native feet, however, are not like European ones, and Mr. Richardson, the chief engineer of the ship, mentioned that he had himself seen elsewhere natives standing unconcerned with naked feet on the cover of pipes conveying steam at about 300° F. where no European foot could even lightly rest for a minute. The stones then were hot. The crucial question was, *how* hot was the upper part of this upper layer on which the feet were to rest an instant in passing? I could think of no ready thermometric method that could give an absolutely trustworthy answer, but I could possibly determine on the spot the thermal equivalent of one of the hottest stones trodden on. (It was subsequently shown that the stone might be much cooler at one part than another.) Most obviously, even this was not an easy thing to do in the circumstances, but I decided to try to get at least a trustworthy approximation. By the aid of Chief Engineer Richardson, who attended with a stoker and one of the quartermasters, kindly detailed at my request by the ship's master, Captain Lawless, I prepared for the rough but conclusive experiment presently described.

It was now nearly forty minutes after four, when six acolytes (natives), wearing crowns of flowers, wreathed with garlands and bearing poles nearly fifteen feet long, ostensibly to be used as levers in toppling over the upper stones, appeared. They were supposed to need such long poles because of the distance at which they must stand on account of the heat radiated from the pile, but I had walked close beside it a moment before and satisfied myself that I could have manipulated the stones with a lever of one-third the length, with some discomfort, but with entire safety. Some of the uppermost stones only were turned over, leaving a superior layer, the long poles being needlessly thrust down between the stones to the bottom, where two of them caught fire at their extremities, adding very much to the impression that the exposed layer of stones was red hot, when in fact they were not, at least to the eye. These long poles and the way they were handled were, then, a part of the ingenious "staging" of the whole spectacle.

Now the most impressive part of the ceremony began. Papa-Ita, tall, dignified, flower-crowned and dressed with garlands of flowers, appeared with naked feet and with a large bush of "Ti" leaves in his hands, and, after going partly around the fire each way uttering what seemed to be commands to it, went back and beating the stones nearest him three times with the "Ti" leaves, advanced steadily, but with obviously hurried step, directly over the central ridge of the pile. Two disciples, similarly dressed, followed him, but they had not the courage to do so directly along the heated centre. They followed about half-way between the centre and the edge, where the stones were manifestly cooler, since I had satisfied myself that they could be touched lightly with the hand. Papa-Ita then turned and led the way back, this time with deliberate confidence, followed on his return by several new disciples, most of them not keeping exactly in the steps of the leader, but obviously seeking cooler places. A third and fourth time Papa-Ita crossed with a larger following, after which many Europeans present walked over the stones without reference to the priest's instructions. The natives were mostly in their bare feet. One wore stockings. No European attempted to walk in bare feet except in one case, that of a boy, who, I was told, found the stones too hot and immediately stepped back.

The *mise en scène* was certainly noteworthy. The site, near the great ocean breaking on the barrier reefs, the excited crowd, talking about the "red-hot" stones, the actual sight of the hierophant and his acolytes making the passage along the ridge where the occasional tongues of flame were seen at the centre, with all the attendant circumstances, made up a scene in no way lacking in interest. Still, the essential question as to the actual heat of these stones had not yet been answered, and after the fourth passage I secured Papa-Ita's permission to remove, from the middle of the pile, one stone which from its size and position every foot had rested upon in crossing, and which was undoubtedly at least as hot as any one of those trodden on. It was pulled out by my assistants with difficulty, as it proved to be larger than I had expected, it being of ovoid shape with the lower end in the hottest part of the fire. I had brought over the largest wooden bucket which the ship had, and which was half-filled with water, expecting that this would cover the stone, but it proved to be hardly enough. The stone caused the water to rise nearly to the top of the bucket, and it was thrown into such violent ebullition that a great deal of it boiled over and escaped weighing. The stone was an exceedingly bad conductor of heat, for it continued to boil the water for about twelve minutes, when, the ebullition being nearly over, it was removed to the ship and the amount of evaporated water measured.

Meanwhile others, as I have said, began to walk over the stones without any reference to the ceremony prescribed by Papa-Ita, and three or four persons, whom I personally knew on board the ship, did so in shoes, the soles of which were not burned at all. One of the gentlemen, however, who crossed over with unburned shoes, showed me that the ends of his trousers had been burnt by the flames which leaped up between the stones, and which at all times added so much to the impressiveness of the spectacle, and there was no doubt that any one who stumbled or got a foot caught between the hot stones might have been badly burned. United States Deputy-Consul Ducorran, who was present, remarked to me that he knew that Papa-Ita had failed on a neighbouring island, with stones of a marble-like quality, and he offered to test the heat of these basaltic ones by seeing how long he could remain on the hottest part of the pile, and he stood there, in my sight, from eight to ten seconds before he felt the heat through the thin soles of his shoes beginning to be unpleasantly warm.

A gentleman present asked Papa-Ita why he did not give an exhibit that would be convincing by placing his foot, even for a few seconds, between two of the red-hot stones which could be seen glowing at the bottom of the pile, to which Papa-Ita replied with dignity, "My fathers did not tell me to do it that way." I asked him if he would hold one of the smaller, upper hot stones in his hand. He promised to do so, but he did *not* do it.

The outer barriers were now removed and a crowd of natives pressed in. I, who was taking these notes on the spot, left, after assuring myself that the stones around the edge of the pit were comparatively cold, although the centre was no doubt very hot, and those below red hot. The real question is, I repeat, how hot were those trodden on? and the answer to this I was to try to obtain after measuring the amount of water boiled away.

On returning to the ship this was estimated from the water which was left in the bucket (after allowing for that spilled over) at about ten pounds. The stone, which it will be remembered was one of the hottest, if not the hottest, in the pile, was found to weigh sixty-five pounds, and to have evaporated this quantity of water. It was, as I have said, a volcanic stone, and on minuter examination proved to be a vesicular basalt, the most distinctive feature of which was its porosity and non-conductibility, for it was subsequently found that it could have been heated red hot at one end, while remaining comparatively cool at the top. I brought a piece of it to Washington with me and there determined its specific gravity to be 0·39, its specific heat 0·19 and its conductivity to be so extremely small that one end of a small fragment could be held in the hand while the other was heated indefinitely in the flame of a blow-pipe, almost like a stick of sealing-wax. This partly defeated the aim of the experiment (to find the temperature of the upper part of the stone), since only the mean temperature was found. This *mean* temperature of the hottest stone of the upper layer, as deduced from the above data, was about 1200 degrees Fahrenheit, but the temperature of the surface must have been indefinitely lower. The temperature at which such a stone begins to show a dull red in daylight is, so far as I am aware, not exactly determined, but is approximately 1300 to 1400 degrees Fahrenheit.

To conclude, I could entertain no doubt that I had witnessed substantially the scenes described by the gentlemen cited, and I have reason to believe that I saw a very favourable specimen of a "Fire Walk."

It was a sight well worth seeing. It was a most clever and interesting piece of savage magic, but from the evidence I have just given I am obliged to say (almost regretfully) that it was not a miracle. S. P. LANGLEY.

Smithsonian Institution, Washington, D.C., August 7.

The Size of the Ice-grain in Glaciers.

IN referring to the size of the grain of the glacier in the chapter on chemistry and physics in the "Antarctic Manual," I have given 700 grammes as the maximum weight which I have observed. In August, 1895, I made an extended study of the structure of glacier ice, principally from the Aletsch Glacier. The fragments of this glacier, which float as icebergs in the Mergelin See, are exposed to the powerful weathering influence of the summer sun, and are comparatively easily dissected into their constituent grains. A number of blocks were so dissected in order to ascertain the weight and size of the largest grains. The following weights of single grains were determined:—700, 590, 450, 270, 255, 170, 155 and 100 grammes. It was observed that blocks of ice contained grains of all sizes, which fitted each other so exactly that, in the fresh unweathered block, the whole volume was filled with ice.

It was not then thought necessary to determine the weight of the smaller grains. On revisiting the Mergelin See in the latter part of July of this year, I dissected several blocks of ice more or less completely and weighed their constituent grains. In order to effect the dissection a powerful sun is requisite, and a powerful sun means a high atmospheric temperature, under the influence of which the small grains melt and disappear very quickly. All the grains in the block are melting at the same time, but the smaller the grain the greater is the ratio of its external surface to its mass. Therefore the weights of the large grains are reduced in a less degree than those of the small ones. Hence it is impossible to furnish an exact statistical account of any block of ice, but the figures in the following tables give a very fair idea of the structural composition of the ice examined. The analyses of blocks E and F are the most complete.

The first block, A, is from the lower end of the Glacier des Bossons in the Chamonix valley, and it was examined on July 17, 1901, which was one of the hottest days of that very hot week. The other blocks are all from the Aletsch Glacier, as they are found floating in the Mergelin See, the waters of which are retained at one end by the ice of that glacier. The Aletsch Glacier is the largest in Switzerland and it contains the largest ice-grains that I have met with. Different parts of the glacier, even in the immediate vicinity of the lake, are of different grain, and the fragments are easily distinguished as they float in the water. Thus block F is a block of large grained ice, while E is of comparatively small grained ice, though it is by no means of the smallest grain.

List of blocks dissected.

Block A.—Chamonix, July 17, 1901. From the end of the Glacier des Bossons.

Blocks B, C and D were taken from the Mergelin See on July 21, 1901, and exposed to the sun on a rock for some hours. B and C were then dissected, though not completely; that is, a certain comparatively small portion of each of them remained undissected. D was dissected only in so far as to enable a prominent and very large grain (570 grm.) to be removed and weighed. The remainder was left till the next day. Owing to the high temperature of the air both by night and by day, its size was very much reduced. It is called Block *d*, and it was dissected on July 22, 1901.

Block E from the Mergelin See was collected and dissected on July 22, 1901.

Block F had suffered far-reaching sun weathering. It was not removed from the lake, but was dissected in the water on July 24, 1901.

The results are embodied in the two following tables. All the

weights are given in grammes. They were determined on a Salter's spring balance which carried 500 grammes, and its scale was divided into intervals of 10 grammes each. Ice-grains which weighed more than 500 grammes were divided in two.

As has been already pointed out, the figures in the tables do not give an exact statistical account of the blocks of ice. The smallest grains have most frequently escaped being weighed, therefore the average size of the grain comes out higher than the truth. The figures in the tables give a general idea of the constitution or anatomy of a block of ice taken from the lower part of a large glacier. They are particularly interesting when we reflect that every grain, even the largest, has grown, according to the rigid laws of crystallomorphic development, from a single snow crystal which probably weighed no more than one or two centigrammes.

In the Mergelin See, glacier ice can be studied in a way that is possible in no other place. The fragments of the Aletsch Glacier which float in it are veritable icebergs, and behave in the same way as their relatives in the Arctic or Antarctic Ocean. In the middle of summer, however, they are exposed to a much more powerful sun than either the northern or the southern bergs. Consequently, the weathering and disintegration, as well as the melting, proceed at a much more rapid rate.

The action of the sun's rays on glacier ice is twofold; it disarticulates the ice into its constituent grains, and it splits the individual grain up into laminæ perpendicular to the principal axis of the crystal and bounded by the planes of fusion discovered and described by Tyndall. These planes are the distinguishing characteristic of the individual ice-grain.

Under the influence of radiant heat an ice-crystal begins to melt at the surfaces which separate these laminæ, and the process of disintegration and decay is directed by their plane. On the other hand, an ice-crystal, floating in water and losing heat, generates ice laminæ which are directed by the same planes, which form the continuation of the corresponding laminæ of the parent crystal. This was well observed at the end of August, 1895. Every night a thin skin of ice was formed at the shallow end of the lake, where the ice blocks are collected. As the grains in a block of glacier ice are distributed quite irregularly, the water line of a floating block necessarily cuts a great number of grains, all of which are oriented differently. The ice which was formed during the night along this line was oriented crystallographically by the grain with which it was in contact and from which it appeared to spring in continuation of its crystalline laminæ. This produces a remarkable pattern of lines on the surface of the lake ice contiguous to a block of glacier ice.

Tyndall has described and figured the minute features of the disintegration of the crystal under the absorption of radiant heat. Similar and complementary features are observed when ice is generated from an existing crystal under the dissipation of heat. To do justice to them, however, would require the services of a skilful, patient and resourceful artist.

The disarticulating and analysing action of the sun's rays is not accomplished without the selection and expenditure of energy. Accordingly we observe that one grain protects another. The disarticulation into separate grains, although very thorough near the surface of a glacier, does not penetrate far. A stroke or two with an ice axe reveals the fresh blue ice. The analysis of the individual grain into crystallographically oriented laminæ can be particularly well studied in the Mergelin See. It is only the grains that are exposed to the sky, and above water, that are so analysed; and prolonged exposure of this kind reduces a grain to the last stage of dilapidation. The grains beneath the surface, *whether of ice or water*, are almost completely unattacked.

The importance, or rather the necessity, of direct sky-light for the disarticulation of glacier ice into its constituent grains is very well seen in the artificial grottoes which are maintained at easily accessible parts of most popular glaciers. The thickness of the layer of completely disarticulated ice is so small that it is hardly noticed, and the whole grotto appears to be cut out of pure blue ice. If the observer, on penetrating for a few paces, turns round and looks outwards, he sees the surface of the ice-walls of the grotto etched with strange line-figures. These are most strongly marked near the opening, and they cease exactly at the spot where the last ray of direct sky-light strikes the ice. The lines so developed are formed by the intersection of the surface of the ice-wall of the cave with the separating surfaces of contiguous ice-grains. The photographic picture thus presented is one of very great interest.

It is only perfectly pure water, received directly as it flows from the still, that can be frozen into homogeneous glass-like ice. All natural ice proceeds from impure water.

In lake ice of moderate thickness the crystalline axis is perpendicular to the surface of the lake. Consequently, Tyndall's planes of fusion are parallel to this surface. When exposed to a powerful sun, and with an air temperature even much below 0° C., the ice weathers into horizontal laminæ separated by Tyndall's planes of fusion, and into vertical columns. The column in lake ice and the grain in glacier ice are homologous features. They express the form which the individual crystal takes in these different varieties of natural ice.

Were it not for the fact that a glacier is made up of distinct grains of ice, and that this substance has the property of melting and freezing at different temperatures, according to the composition of the water with which it comes in contact and to the pressure to which it is subjected, there is little doubt that a glacier would be as motionless as any other mass of crystalline rock. J. Y. BUCHANAN.

August 6.

Problems of Geometry.

IN Klein's "Famous Problems of Elementary Geometry," geometrical proofs are given for solving the problems of "the duplication of the cube" and "the trisection of an angle" by means of the *cissoid* and the *conchoid* respectively. I find, however, that in "Chambers' Encyclopædia" it is stated, without proof, that the *cissoid* and the *conchoid* are capable of furnishing geometrical constructions for the solution of *both* problems. Can any of your readers furnish me with the necessary references, or supply a proof of the "trisection of an angle" by means of the *cissoid*, and of the "duplication of the cube" by means of the *conchoid*? A. B. BASSET.

Fledborough Hall, Holyport, Berks, August 9.

Forecast and Fact.

IN NATURE of January 12, 1893 (p. 246), I represented as probable an early descent of the smoothed curve of rain days at Greenwich, there given, "and a commencing series of (on the average) drier summers than we have had lately."

The following table may now be compared with this:—

	Rf. Summer.	Relation to av. (6·81)
1893	5·40	−1·41
1894	8·33	+1·52
1895	5·74	−1·07
1896	5·07	−1·74
1897	5·52	−1·29
1898	3·95	−2·86
1899	2·85	−3·96
1900	6·26	−0·55

Per contra, there is the chastening reflection that a rule which held good (with one exception) since 1815 (see *Symons' Met. Mag.*, June 1898, p. 70), and which was quoted in your columns, has broken down on this occasion, viz. that in the group of five summers ending with a sunspot minimum, there are more wet summers than dry! A. B. M.

Boomerangs.

IN relation to the interesting article on boomerangs in your issue of August 1, it may perhaps be of interest to some of your readers to know that Schiaparelli, in his famous book, "Entwurf einer astronomischen Theorie der Sternschnuppen," p. 13, speaks of "bumerangs." He says:—"Very likely the *cateja* described by Isidor of Seviglia was nothing but a sort of bumerang." "Est genus Gallici teli, ex materia quam maxime lenta, quæ jacta quidem non longe propter gravitatem evolat, sed quo pervenit, vi nimia perfringit: quod si ab artifice mittatur, rursus redit ad eum qui misit." Isidori Hispalensis, Origg, xviii. OTTAVIO ZANOTTI BIANCO.

Torino (Italy) Via della Rocca 28.

BATRACHIANS AND REPTILES IN THE CAMBRIDGE NATURAL HISTORY.[1]

IN the preface to this welcome volume the author reminds his readers of the words of Linnæus, "Amphibiologi omnium paucissimi sunt nullique veri." What progress has been accomplished by the "Amphibiologi"—herpetologists we now term them—in dealing with the "pessima tetraque animalia" during the 150 years which have elapsed since this statement of the great naturalist cannot be better realised than by a perusal of the excellent contribution supplied by Dr. Gadow for the eighth volume of the "Cambridge Natural History."

This work is not only of the highest interest in bringing together in a small compass and in a charming style the essence of a most voluminous literature; it derives special value from the authority of its writer as an anatomist and observer of the Batrachians and Reptiles both in their native haunts and in the vivarium.

Not content with giving us the benefit of his wide experience in the departments to which he has devoted so much study, Dr. Gadow has also suggested various reforms in the general classification, thus raising the work far above the usual standard of this kind of semi-popular treatises.

The following table will show the classification adopted, and which, on the whole, reflects so well the state of our present knowledge. The author explains in the preface that the principal groups are called subclasses in order to emphasise their taxonomic importance in comparison with the main groups of birds and mammals:—

	Subclass	Order	Suborder
Amphibia	Stegocephali	Lepospondyli	Branchiosauri, Aistopodes
		Temnospondyli	
		Stereospondyli	
	Lissamphibia	Apoda	
		Urodela	
		Anura	Aglossa, Phaneroglossa
Reptilia	Proreptilia		
	Prosauria	Microsauri	
		Prosauri	Protorosauri, Rhynchocephali
	Theromorpha	Pareiasauri	
		Theriodontia	
		Anomodontia	
		Placodontia	
	Chelonia	Atheca	
		Thecophora	Cryptodira, Pleurodira, Trionychoidea
	Dinosauria	Sauropoda	
		Theropoda	
		Orthopoda	Stegosauri, Ornithopodi
		Ceratopsia	
	Crocodilia	Pseudosuchia	
		Parasuchia	
		Eusuchia	
	Plesiosauria	Nothosauri	
		Plesiosauri	
	Ichthyosauria	Ichthyosauri	
	Pterosauria	Pterosauri	Pterodactyli, Pteranodontes
	Pythonomorpha	Dolichosauri	
		Mosasauri	
	Sauria	Lacertilia	Geckones, Lacertæ, Chamæleontes
		Ophidia	

The boldest attempt at innovation in taxonomy consists in the removal from the class Batrachia or Amphibia, as generally understood, to that of Reptilia, not only of the Microsauria, but of a number of other members of Cope's Stegocephalia. But this change is not one that is likely to commend itself. We all know how, in the light of recent palæontological discovery, most of the supposed distinctive features of the two classes in question have faded away, as instanced by Prof. Seeley's proposal to unite the Stegocephalia with the Reptiles, and Prof. Credner's establishment of the group Eotetrapoda for the reception of the earlier Batrachians and Reptiles. However, one thing appears certain to me: the Stegocephalia, as defined by Cope, form one compact group, distinguished from both Batrachians proper and Reptiles by the presence of additional dermal bones in the skull—the occipital (dermo-occipital) and the so-called "epiotic," which I regard as the homologue of the post-temporal of Fishes—and, further, in all cases where the pectoral arch is known, by their conforming to the type of the Crossopterygian and early Ganoid Fishes in the possession of the element termed cleithrum by Gegenbaur (clavicle of ordinary Teleosts) in addition to the clavicle proper. These highly important features, connecting the Crossopterygians with the Stegocephalians, are relegated to the background by Dr. Gadow, who prefers to establish the turning-point where to part the Reptilian phylum from the Batrachian upon the constitution of the elements of the vertebral column, Batrachians being defined as *acentrous*, *pseudocentrous* or *notocentrous*, that is to say, in which the author's "dorsal arcualia" are reduced or absent, Reptiles as *gastrocentrous*, the centra of the vertebræ being formed by pairs of "interventralia," while the "basiventralia" (intercentra of Cope) are reduced, persisting either as wedgebones or as intervertebral pads, or absent. This is the application of the views set forth by the author in his well-known paper published in the *Philosophical Transactions* for 1896; but it must be admitted that, so far as the Stegocephalia are concerned, the ideal distinction between interdorsalia and interventralia cannot be practically applied, owing to the types which connect *Eryops*, now proposed to be placed with the Reptiles together with the Embolomeri and Microsauria, and *Archegosaurus*, associated with the Labyrinthodonts. Whatever measure of truth Dr. Gadow's theory of the evolution of the vertebral column may contain, it is very doubtful whether any students of the fossil remains will be able to agree with him in regarding the composition of the tripartite vertebræ of these genera as due to "superficial resemblance." "After all," the author adds (p. 285), "we feel certain that Reptiles have arisen from Stegocephalous Amphibia, and it is in the Lower Permian, exactly where the debatable creatures lived side by side with the Stegocephali, undoubtedly likewise temnospondylous, that the change from Amphibia into Reptiles seems to have taken place."

It is highly probable that the Stegocephalians will be found to have been derived from the Crossopterygians and to lead, on the one hand, to the Batrachians through the Branchiosauria, and, on the other hand, to the Reptiles through the Microsauria. Perhaps the best means of getting over the difficulty with which we are confronted would be to raise the Stegocephalians to the rank of a class, which is quite capable of exact definition. But there is certainly no sufficient justification at present for the proposal to unite *Eryops* and the *Embolomeri* (*Proreptilia* of Gadow) with the Reptiles rather than with the Batrachians.

I would add that if Dr. Gadow thus repudiates the classification of Cope, it is contrary to the rules of nomenclature to make use in the sense he does of the name *Stegocephali*.

On the other hand, I hail with satisfaction the

[1] Amphibia and Reptiles. By Hans Gadow. "The Cambridge Natural History." Vol. viii. Pp. xiii + 668; 181 woodcuts. (London: Macmillan and Co., Ltd.) Price 17s. net.

systematic position given to the Apoda or Cæcilians (which name should not have been spelt Cœcilians).

In the division of the Anura or Ecaudata an attempt is made at reducing the number of families, but it is difficult to see what is to be gained by this reduction in a manner for which the author himself pleads guilty of inconsistency; a reproach which would apply likewise to some changes in the classification of the Lacertilia.

FIG. 1.—Australian tree-frog (*Hyla caerulea*).

In accordance with what I believe to be the duty of a reviewer, however more disposed he may feel to praise than to criticise, a certain prominence should be given to the pointing out of small errors, such as necessarily creep in all books of some extent, in order to prevent their propagation, especially in the case of a work which is certain to enjoy a wide circulation. I have, therefore, here noted a few which I have come across.

P. 11. The number of caudal vertebræ varies much in our species of newts. It might mislead the student in search of additional characters by which to distinguish *Triton palmatus* from *T. taeniatus* to read that the latter has about a dozen vertebræ more than the former.

P. 30. *Pelobates* cannot be described as a "very aquatic" genus. On the same page, *Amphodus* should have been mentioned as the best example of a frog with toothed parasphenoid.

P. 45. There is no difference in the nature of the external gills of *Protopterus* and *Lepidosiren*.

P. 95. On the map showing the distribution of the Urodela, the range of these Batrachians should be extended to Ireland, Southern Norway, Syria, Northern Persia and Peru. The habitat of *Plethodon platensis*, mentioned on p. 94, is not marked on the map.

P. 153. The tympanum is often very distinct in *Discoglossus*.

P. 161. The map does not show the eastern extension in Europe and to South-western Asia of the *Pelobatidae*, nor is it correct as to the distribution of the *Pelobatidae* and *Discoglossidae* in Eastern Asia and North America (cf. pp. 153, 162, 164, 165).

P. 167. The common toad occurs in Norway as far as 65° lat., as correctly stated on p. 177; but this is not shown on the map.

P. 189. The pupil is horizontal in *Diaglena* (as the name implies) and *Pternohyla*.

P. 198. The curious *Hyla goeldii* is from the Serra dos Orgãos, not from Pará.

P. 288. "Deeply amphicœlous vertebræ" is not true of all "Prosauria" (cf. *Hyperodapedon* and *Sauranodon*, the latter with procœlous vertebræ).

P. 332 (map). Testudinidæ, Cinosternidæ and Chelydridæ occur in Ecuador.

P. 499. The shell of the egg of *Lacerta viridis* and *L. agilis* is not hard like Geckos', but parchment-like, as described on p. 555, whilst that of *L. vivipara* is a mere membrane.

P. 500. The Scincidæ are represented by several species in New Zealand.

P. 501. Chameleons exist on the Seychelles (*Chamaeleon sechellensis*) and Mauritius.

P. 514. The Pygopodidæ cannot be described as leading a usually subterranean life, any more than our common slow-worm.

P. 529. The map showing the distribution of Anguidæ and Iguanidæ is not quite correct, since the former are represented in South-eastern China (*Ophisaurus harti*) and the latter extend to the South-eastern United States (*Anolis*, *Sceloporus*, *Phrynosoma*), as stated in the text.

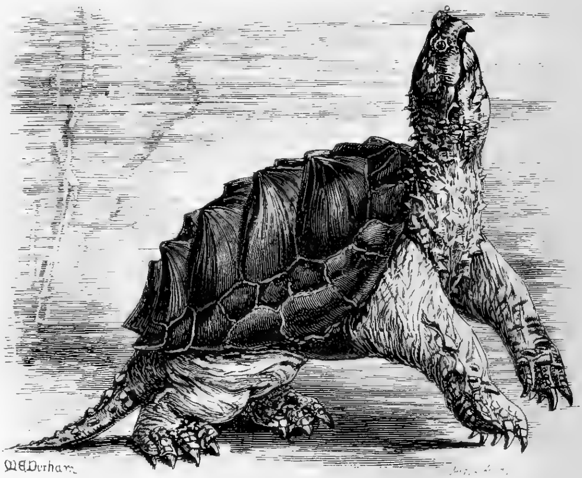

FIG. 2.—"Alligator turtle" (*Macroclemmys temmincki*).

P. 558. The Faraglione Rock near Capri is not blackish.

P. 565. The Amphisbænidæ are represented on the map as occurring all over Africa; but none are known from north of 12° lat. N. except the Mediterranean forms confined to the Atlas and the territory between it and the sea.

P. 644. The range of the *Crotalinae* extends to Celebes (*Lachesis wagleri*).

In matters of nomenclature, some inconsistency is displayed in the termination of the names of orders and suborders, and the use of the term "Sauria" for a group embracing lizards and snakes is unjustifiable.

The illustrations are for the greater part original, and many are actually taken from living specimens. So great a training is required to depict properly the attitudes of any class of animals, and especially the often mysterious-looking creatures which form the subject of the book under review, that only artists who have made a speciality of it can be expected to furnish nearly faultless work, which even then may be spoilt to a certain extent, so far as technical details are concerned, through the intervention of the engraver if, as in the present case, his services have also to be enlisted. It will, therefore, not be unnatural if an expert may find fault with a few of the illustrations in this book. For instance, Fig. 23 represents a difference between the heads of the male and female crested newt which does not really exist; Fig. 31 shows *Bombinator igneus* with the eyes much too far apart, Fig. 91 a *Trionyx* with azygous frontal bone, and Fig. 103 a ventral view of the hand of *Ptychozoon* with the inner finger longer than the outer, which is just the reverse of nature. But all the figures are marked by a freshness which makes up for any shortcomings, and many may be pronounced as exceptionally good.

In concluding the review I would express the opinion that by this handsome volume a very important addition to science has been made; that the beautiful illustrations, together with the clear and charming accounts of the life-histories which it contains, will do much to popularise the study of a rather neglected section of zoology; and that lovers of Reptiles, of which there are more than one generally thinks, will feel that the new knowledge imparted to them emanates from one who is thoroughly in sympathy with their enthusiasm. G. A. BOULENGER.

THE FORTHCOMING MEETING OF THE BRITISH ASSOCIATION.

IN the two articles which have already appeared (May 23 and July 18) upon the meeting of the British Association, to be held at Glasgow on September 11–18, the general arrangements made for the scientific and social pleasures of the members have been described. It is now possible to give an epitome of the programme of the meeting and a forecast of the work of the sections. The sections do not meet on September 11 and September 19, but on all intervening days.

Epitome of Programme.

Wednesday, September 11.—President's address in St. Andrew's Hall.

Thursday, September 12.—Conference of delegates of corresponding societies; inauguration of new anatomical buildings at the University, and the opening of the museum in connection therewith; reception and conversazione in the City Chambers, by invitation of the Lord Provost and Corporation of Glasgow.

Friday, September 13.—Garden party at Overtoun, Dumbartonshire, by invitation of the Lord and Lady Overtoun; lecture in St. Andrew's Hall, by Prof. W. Ramsay, F.R.S., subject: inert constituents of the atmosphere; smoking concert in Berkeley Hall of St. Andrew's Halls.

Saturday, September 14.—Excursions; lecture to artisans in St. Andrew's Halls, by Mr. H. J. Mackinder, subject: the movements of men by land and sea.

Sunday, September 15.—Official sermon in the Cathedral, by the Rev. Pearson M'Adam Muir.

Monday, September 16.—Garden party in the Botanic Gardens and Queen Margaret College, Glasgow, by invitation of the Lord Blythswood, president of the Glasgow Philosophical Society, and Lady Blythswood; lecture in St. Andrew's Hall, by Mr. Francis Darwin, F.R.S., subject: movements of plants.

Tuesday, September 17.—Special visits to public works; conference of delegates of corresponding societies; conversazione in the Exhibition Buildings, by invitation of the president, the chairman and the executive council of the Glasgow International Exhibition Association, 1901.

Wednesday, September 18.—Concluding general meeting; excursion to Paisley and luncheon in the Town Hall, by invitation of Sir Thomas Glen Coats, Bart.; reception and conversazione in the galleries of the Royal Scottish Society of Painters in Water Colours, 153, Sauchiehall Street, by invitation of the president (Sir Francis Powell, P.R.W.S.) and the council; "at home" in the Art Club, by invitation of the president (Mr. J. E. Christie) and the committee of the Glasgow Art Club; reception and conversazione in the Glasgow School of Art, by invitation of the chairman (Mr. James Fleming) and the governors; reception and conversazione in the galleries of the Royal Glasgow Institute of the Fine Arts, by invitation of the president (Sir John Stirling-Maxwell, Bart., M.P.) and the council of the Institute; annual inspection and dinner of the Clyde Navigation Trustees, to which a selected number (probably thirty) of members of the British Association will be invited; dinner by the Faculty of Physicians and Surgeons to a selected number of the medical members of the British Association.

By kind permission of the owners, a large number of shipbuilding yards, public works, &c., in Glasgow and district will be available to the inspection of members during the meeting. Details as to days and times are given in a special handbook and guide that is being prepared by the local committee.

In addition to the information given in NATURE of July 18 with regard to the sectional meetings, the following provisional programmes of sections have been received.

The president's address to Section B (Chemistry) will be on the position of British chemistry at the dawn of the twentieth century. In this address Prof. Percy Frankland, F.R.S., will direct attention to the factors which have been instrumental in promoting the growing activity in original investigation during the past twenty years. He will also point out the disadvantages at the present time incidental to university education, and will indicate some of the more important reforms which are required in the immediate future. Other papers which have been arranged for this Section are, bridged rings, by Prof. Perkin; the present position of electrochemical industries in this country and abroad, by Dr. Shields; the chemical exhibits at the Glasgow Exhibition, by Dr. Lewkowitsch; and ocean salt deposits, by Dr. E. F. Armstrong. The last paper may possibly be read at a joint meeting of Sections B and C. Prof. Letts will read papers on the chemical changes which occur during the contact of sewage with "bacteria beds," and on the assimilation of ammonia by the seaweed *Ulva latissima*.

In addition to Mr. J. Horne's presidential address, on recent advances in Scottish geology, to Section C (Geology), the following papers, among others, will be read:—On the volcanic episodes in the geological history of Arran, by Mr. William Gunn; (1) relation of the Old Red Sandstone of north-west Ireland to the Metamorphic rocks, (2) relation of the Silurian and Ordovician rocks of north-west Ireland to the Metamorphic series, by Messrs. A. McHenry and J. R. Kilroe; on a new method in the investigation of fossil remains, Prof. J. W. Sollas; (1) phosphatic nodules, &c., in Upper Carboniferous Limestone of west Yorkshire, (2) a silicified plant seam beneath the Millstone Grit of Swarth Fell, by Mr. John Rhodes; plants and Coleoptera of Pleistocene age from Wolvercote, Oxfordshire, by Mr. A. M. Bell; origin of gravel-flats of Surrey and Berkshire, by Mr. H. W. Monckton; (1) the distribution of fishes in the Carboniferous rocks of Scotland, (2) the fish fauna of the Old Red Sandstone of Scotland, by Dr. Traquair, F.R.S.; the Cambrian fossils of the north-west Highlands, by Mr. B. N. Peach, F.R.S.; fossil plants from Berwickshire, by Mr. R. Kidston; sequence of Tertiary igneous rocks of Skye, by Mr. A. Harker; the Scottish ores of copper and their geological relations, by Mr. J. G. Goodchild; recent observations among the volcanic rocks of Mull, by Sir Archibald Geikie; on Eastern Highland schists, by Mr. G. Barrow; on rock specimens from Perim, by Miss C. A. Raisin.

The address of the president of Section D (Zoology) (Prof. J. Cossar Ewart, F.R.S.), on the experimental study of variation, will be given on Thursday, September 12. The preliminary list of papers to be read shows that from a zoological point of view the Glasgow meeting will be one of exceptional interest; while the proximity of the Firth of Clyde and the establishment of the marine biological station at Millport will provide attractions of a special character for the marine biologist. The committee have invited lectures from Major Ronald Ross, F.R.S., on tropical parasitology, giving the results of his most recent investigations; and from Dr. J. E. S. Moore, on the problem of Lake Tanganyika. Both gentlemen have consented, subject, in the former case, to Major Ross's expected return from Africa in time. In addition to the above, Prof. J. Arthur Thomson will read a paper on germinal selection in its relation to inheritance; Mr. E. J. Bles, on a method of recording local fauna; Mr. L. A. Borradaile, on the land crabs of Minikoi; Mr. J. S. Budgett, on the youngest known larva of *Polypterus*; Mr. J. Graham Kerr, on the origin of vertebrate limbs; Mr. J. Y. Simpson, on variation in relation to binary fission in Protozoa; and Dr. T. H. Bryce, on heterotypical division in the maturation of sexual cells. These titles indicate the main outlines of the zoological programme, but the committee have not yet finally closed their list. A joint discussion with Sections C and E on limnology is provisionally arranged for Monday, September 16.

In Section E (Geography) the president's address will be delivered on Thursday, September 12, at 10.30 a.m., and will deal specially with the study of geography, as distinct from the teaching of that subject, in this country. Amongst the papers which it is hoped will be communicated to the Section during the meeting are:—Mr. G. G. Chisholm, geographical conditions affecting British trade; Mr. E. G. Ravenstein, Martin Behaim and his globe of 1492; Dr. A. J. Herbertson, a morphological map of Europe; Dr. R. Bell (Geological Survey of Canada), Northern Ontario; Dr. Moreno, on the Argentine Republic; Mr. W. N. Shaw, on weather maps; Mr. H. N. Dickson, on mean temperature and glacial periods; Dr. R. Logan Jack, on travels in Western China; Mr. Yule Oldham, on the Bedford level experiments. Captain Lemaire will give an account of his recent expedition. Special attention will be directed to the geography of Scotland, and it is hoped that Sir A. Geikie will read a paper on some questions relating to this subject; Mr. G. F. Scott Elliott has promised a paper on the effects of vegetation in the valley and plains of the Clyde; Dr. Marion Newbigin, on the proposed survey of the Forth valley, undertaken by the Scottish Natural History Society; and Mr. W. G. Smith, on the methods of the Botanical Survey of Scotland inaugurated by his brother, the late Mr. R. A. Smith. Papers will probably be read on the British and German Antarctic expeditions, and Mr. W. S. Bruce has promised a paper on the methods and plans of the Scottish Antarctic Expedition. It is hoped that a joint discussion may be arranged with other sections on the objects and methods of limnology. Sir Thomas Holdich will present the report of the committee on surveys of British Protectorates, and the reports of committees on the climate of Tropical Africa and on surveys of the Phlegræan Fields will also be read.

In Section G (Engineering), the provisional programme includes the following papers:—Address of the president, Colonel R. E. Crompton, on (*a*) modern development of passenger and goods traffic, as affecting carriage on railways, tramways and ordinary roads; (*b*) standardisation and interchangeability; (*c*) the National Physical Laboratory. Paper by Mr. D. H. Morton on the mechanical exhibits in the Glasgow Exhibition; report of the committee on resistance of road vehicles to traction; the carriage of goods over electric trolley systems, Mr. A. H. Gibbings; railway rolling stock, present and future, Mr. M. N. Macdonald; the Panama Canal, M. Bunau Varilla; tunnelling through quicksands, M. A. Gobert; the protection of public buildings from lightning, Mr. Killingworth Hedges; the Diesel engine, Herr Rudolf Diesel; aluminium, Prof. E. Wilson; aluminium as a fuel, Sir W. C. Roberts-Austen, K.C.B., F.R.S.; report of the committee on the small screw gauge; recent developments of chain driving, Mr. C. R. Garrard; the critical point in rolled steel joists, Mr. E. T. Edwards; machinery for engraving, Mr. Mark Barr; measurement of the hardness of materials by indentation by a steel sphere, Mr. T. A. Hearson.

Prof. D. J. Cunnningham, F.R.S., the president of Section H (Anthropology), will take as the subject of his address the human brain, and the part which it has played in the evolution of man; and papers on physical anthropology are likely to be more prominent this year than on some previous occasions. Special attention will be directed to recent work by Dr. Brown and Mr. Gray on the physical characteristics of the people of Ireland and Scotland respectively; Mr. Douglas, Superintendent of Police at Glasgow, promises an account of the anthropometric method of identification as practised locally; and other papers on Egyptian and Papuan anthropology are expected from Drs. Rivers and Myers. Two papers have been received on the natives of the Malay Peninsula, by Mr. Skeat, and Messrs. Annandale and Robinson. Dr. Sturge has a paper on the chronology of the Stone Age of man, and Mr. Arthur Evans will supplement the report of the Cretan Exploration Committee by an account of the Neolithic settlement which underlies the great Mycenæan palace of Knossos. Mr. Hogarth also promises an account of this year's campaign in eastern Crete. The report of the Canadian Ethnographic Survey promises, as before, a variety of subjects for discussion; and it is hoped that special arrangements may be made for the description and examination of the ethnographic and archæological sections of the Glasgow Exhibition; though at present the culture and archæology of the neighbourhood remain quite unrepresented in the programme.

The president of Section I. (Prof. J. G. McKendrick, F.R.S.) will open the work of the section with an introductory address. The feature of the transactions will, however, be a discussion on the subject of phonetics. This is to be introduced by a demonstration from the president of the different methods employed in researches into this subject, after which it is expected that Dr.

Lloyd (Liverpool), Dr. Pipping (Helsingfors), Dr. Boeke (Alkmaar) and others will take part in the discussion.

Communications are also promised from Dr. A. A. Gray (Glasgow), on the cochlea; from Dr. Kennedy (Glasgow), on the repair of nerves; from Dr. Edridge Green, on the classification of the colour blind; from Dr. R. Hutchison, on the chemistry of bone marrow. Other contributions are also promised from workers who have not as yet sent in titles. It is not anticipated, however, that the amount of work will be as great as usual, owing to the fact that many British physiologists are attending the International Congress to be held in Turin a week later than the Glasgow meeting.

A discussion on the teaching of botany will be opened in Section K by Mr. Wager and Prof. Bower from the point of view of school and university teaching respectively. Prof. Miall, Prof. Marshall Ward, Dr. Scott, Prof. Scott-Elliott and others are expected to take part in the discussion. On Friday afternoon, September 13, Prof. Reynolds Green will deliver a semi-popular lecture on flesh-eating plants. The following papers have been promised:—Prof. Bayley Balfour (president), morphological notes; Prof. Marshall Ward, the Bromes and their brown rusts; Mr. Wager, on the cytology of the Cyanophyceæ; Prof. Bower, on an *Ophioglossum* collected by Mr. Ridley; Dr. Lang, on the prothalli of *Helminthostachys*, *Ophioglossum pendulum* and *Psilotum*; on certain large prothalli of *Lycopodium cernuum*; on the mode of occurrence of the prothalli of *L. Selago* at Clova. Mr. Yapp, on two Malayan 'myrmecophilous' ferns; Miss Ford, on the anatomy of *Ceratopteris*; Mr. Brebner, on the anatomy of *Danaea* and other Marattiaceæ; Mr. Seward and Miss Ford, on the structure of *Todea*, and on the geological history of the Osmundaceæ; Dr. Scott, on a primitive type of structure in *Calamites*; Prof. F. W. Oliver, on the structure of certain Palæozoic seeds; Mr. Seward, Jurassic floras; the structure and origin of jet; Mr. Arber, a collection of fossil plants from New South Wales; Dr. F. F. Blackman and Miss Matthaei, autosurgery in leaves; on respiration; Miss Clark, effect of altered conditions of growth upon *Lemna* roots; Mr. Tansley, the vegetation of Mount Ophir; Mr. Yapp, some botanical photographs from the Malay Peninsula; Miss Clark, abnormal secondary thickening in *Kendrickia Walkeri*; Mr. Worsdell, the structure and morphology of the flowers of *Cephalotaxus*; the morphology of the ovule; Mr. Tagg, museum work; Mr. Borthwick, increment of wood; Mr. Gwynne-Vaughan, the vascular anatomy of the Cyatheaceæ; on the nature of the stele of *Equisetum*; Mr. Boodle, remarks on the stele and foliar bundles of ferns.

The new section of Educational Science will be opened on the morning of September 12 with an address by the president, Sir John Gorst. In the afternoon there will be papers and discussions on the organisation of education in Scotland and particularly in Glasgow. On September 13, papers on the science of education will be read by Prof. Armstrong, F.R.S., Prof. Miall, F.R.S., Prof. Withers and others. On Monday, September 16, a discussion on the teaching of mathematics will be introduced by Prof. Perry, F.R.S. On September 17 the subject of discussion will be the influence of universities and examining bodies on the education given in secondary schools, introduced by the Bishop of Hereford and Mr. H. W. Eve.

The committee of the Marine Biological Association of the West of Scotland invite members of the Association who are interested in marine biology to work at or visit the Marine Station, Millport, N.B., any time during September 1901, and to join any of the open collecting excursions of the steam yacht *Mermaid* during that month. The intention should be communicated to the Curator, Marine Station, Millport, N.B.

THE INTERNATIONAL ZOOLOGICAL CONGRESS.

THE fifth International Congress, the proceedings of which have just terminated in Berlin, has, notwithstanding the depression caused by the recent death of the Empress Frederick, been a brilliant and important reunion, whether judged by the number and status of the zoologists present or by the interest of its work.

The meetings were held in the Reichstagsgebäude, corresponding to our Houses of Parliament, a fact which in itself testifies to the esteem in which science is held in Germany.

On the evening of Sunday, August 11, an informal gathering was held at which the delegates and members were able to meet and greet each other, to renew old acquaintances and form new ones. The business of the Congress began on Monday, August 12, in the large hall of the Reichstag, when Prof. Möbius assumed the presidential chair and, after declaring the proceedings open, made a touching reference to the sorrow which had fallen upon the Royal Family, and proposed that telegrams of condolence should be sent to the Emperor and to the Crown Prince, who had graciously consented to act as patron of the assembly. Replies to these messages were subsequently received and read.

The Congress was then welcomed by His Excellency Herr Rothe, Under Secretary of State, in the absence of the Chancellor, by Burgomaster Kirschner and by Prof. Harnack, the Rector of the University. Prof. Perrier expressed the acknowledgments of the foreign delegates, and after some formal business, Prof. Grassi, of Rome, delivered a lecture on "The Malaria Problem from the Zoological Point of View," in which he gave an account of the diseases caused by insect-stings and dwelt upon the importance of their study for the progress of hygiene.

It is usual with us to terminate the proceedings of a congress with a picnic, but the committee charged with the arrangements of the present meeting seem to have thought that the proceedings would be smoother if social intercourse preceded debate, and with this view organised an excursion to the Havel See.

On the Tuesday no forenoon sittings were held, in consequence of the Royal funeral; but at midday a general meeting was held, at which, among other business, it was announced that the prize offered by the Emperor Nicholas II. had been awarded to Dr. Oudemans, of Amsterdam, for his memoir "On the Influence of Light on the Development of Colours in the Lepidoptera."

Dr. Sclater having taken the chair, lectures were delivered on "The Theories of Fertilisation," by Prof. Yves Delage (Paris), who referred to the importance of studying the phenomena, not merely morphologically, but also physiologically; and on "The Psychic Faculties of Ants and other Insects," by Prof. Forel (Morges), in which he sought to show an identity between the senses of insects and our own and to demonstrate their possession of memory, association of sensory impressions and power of drawing conclusions from experience.

A general meeting was also held on Thursday afternoon, August 15, when addresses were given by Prof. E. B. Poulton (Oxford) on "Mimicry," by Prof. Patten (Hanover, U.S.A.) on "The Origin of Vertebrates," Prof. v. Zograf (Moscow) on "Hydrobiological Investigations and Institutes in Russia," M. A. Pizon (Paris) on "The Observation of Budding in Tunicates," Mr. C. G. Schillings (Düren) on "East African Mammals," and Mr. O. Neumann on "Results of a Journey from the Red Sea to the White Nile," all illustrated by the lantern.

At other times the Congress separated into seven sections—viz. General Zoology, Experimental Zoology, Vertebrata (Biology, Classification), Vertebrata (Anatomy, Embryology), Invertebrata, Arthropoda and Nomenclature. These were presided over on successive days by different zoologists of eminence, and such numerous communications were made to each that it is impossible to give an account of these, or even a list of their titles.

The concluding meeting took place on Friday morning, when a large amount of business was transacted. The report of the Nomenclature Commission, which was adopted, included a recommendation that specific and generic names should be amended only when a printer's error or a mistake in orthography could be proved, and that in all cases the first name given to an animal, whether to the whole animal or to a part, to an adult or a larva, should stand, and also a proposal for introducing uniformity into the arrangement of figures on plates and the designation of their parts by explanatory letters. Resolutions were also passed in favour of the preservation of non-injurious animals and the formation of a section for zoogeography; it was, further, decided to hold the next congress in Bern, under the presidency of Prof. Studer. Addresses were given by Prof. Bütschli (Heidelberg) on "Vitalism and Mechanism," and by Prof. Branco (Berlin) on "Fossil Men," and after the usual complimentary resolutions the Congress was adjourned.

Such were in brief the formal proceedings, but, as is always the case, these were by no means the most important results. More far-reaching in their influence on the life and work of zoologists are the informal discussions and friendly conversations which take place in the intervals, on such occasions as the reception by the City of Berlin at the Rathhaus, by the Zoological Society in its magnificent garden and in other more modest convivial gatherings.

The whole meeting was admirably organised, with German thoroughness and attention to detail. It only remains to be added that an appendix to the Berlin meeting took place in Hamburg, where the members were received at the Rathhaus by the Senate of the City, by the directors of the Hamburg-American Line on board the ss. *Graf Waldersee* and by the Zoological Society in their garden. A trip to Heligoland terminated the whole proceedings, which must have left a vivid and pleasant impression on the mind of every one present.

CHARLES A. SCHOTT.

MR. CHARLES A. SCHOTT, whose death we regret to record, was renowned throughout the world of physical science on account of his numerous memoirs on terrestrial magnetism. The work accomplished by him during a long and active career was both extensive and influential, and its value has long been recognised by physicists in both hemispheres.

From an appreciative account of Mr. Schott's work, which appeared in *Terrestrial Magnetism* two years ago, we learn that he was born at Mannheim, Baden, Germany, August 7, 1826. After passing through the public school and partly through the Lyceum of his native town, he entered the Polytechnic School at Karlsruhe, where, after a six-year course, he graduated as civil engineer in 1847. In December of that year he entered the service of the United States Coast Survey, and in due time became a citizen of the United States. At first he was engaged in office and nautical duties, but he was assigned to the position of Chief of the Computing Division of the Survey in 1855. Mr. Schott continued in charge of this until the end of 1899, and he then undertook the discussion of the arc measurements in the United States resulting from the extension triangulation already executed by the different organisations engaged in survey work. A summary of some of the results of this work was given in NATURE of February 21 (vol. lxiii. p. 408).

Mr. Schott's numerous contributions to the annual reports of the Coast Survey since 1854 relating to hydrography, geodesy, practical astronomy, and especially to terrestrial magnestism, are well known. He also published through the medium of the Smithsonian Institution, between the years 1858 and 1881, a number of memoirs bearing on meteorology and on subjects relating to Arctic explorations. He was a member of the Government parties sent to Springfield, Illinois, to observe the solar eclipse of August 1869, and to Catania, Sicily, to observe that of December 1870. As delegate from the United States Coast and Geodetic Survey, he attended the International Conference on Terrestrial Magnetism, held at Bristol in 1898 in connection with the meeting of the British Association. In the same year he received the Henry Wilde prize of 4000 francs from the Paris Academy of Sciences for his numerous contributions to terrestrial magnetism. This was the first award of the prize; and the President of the United States in making the presentation alluded to the catholicity of scientific work and the recognition of distinguished merit implied in the fact that Mr. Schott—an American—should be awarded by French men of science a prize founded by an Englishman. It is encouraging to know that Mr. Schott's zeal and industry for the advancement of natural knowledge met with recognition in the world of science.

NOTES.

A COMMITTEE has been appointed by the President of the Board of Trade to inquire and report as to the best means by which the State or local authorities can assist scientific research as applied to problems affecting the fisheries of Great Britain and Ireland. The members of the committee are as follows:—The Right Hon. Sir Herbert Maxwell, Bart., M.P., Mr. Walter E. Archer, Mr. Donald Crawford, Rev. William Spotswood Green, Prof. William Abbott Herdman, F.R.S., the Hon. Thomas H. W. Pelham, Mr. Stephen E. Spring-Rice, C.B., and Prof. J. Arthur Thomson.

IT has been decided to erect in Leoben, Austria, a statue of Peter Ritter von Tunner, who died on June 8, 1897, to commemorate his great services to the metallurgy of iron. An influential committee has been formed, with Mr. Ignaz Prandstetter as president, Prof. J. G. von Ehrenwerth as vice-president and Prof. Carl Fritz as honorary secretary, to collect subscriptions. At a recent meeting of the council of the Iron and Steel Institute the matter was considered. As a contribution to the memorial could not be voted from the funds of the Institute, the members of council present decided to contribute two guineas each, and Mr. Bennett H. Brough, the secretary, now informs us that he has forwarded to the committee in Leoben contributions of that amount from twenty-six members.

A REUTER message records that the *Lucania*, which left Liverpool on August 10 for New York, was spoken by wireless telegraphy at Nantucket Lightship shortly after 6 p.m. on August 16. The following message, signed by Captain McKay, was among those received on the lightship from the *Lucania*, and then transmitted forty miles to Siasconset, on Nantucket Island:—"All well on board. We are 287 miles from Sandy Hook, with clear weather, and expect to reach New York on Saturday. Please inform Cunard Agents." On reaching port the officers of the *Lucania* reported that the messages from Nantucket were undecipherable aboard ship.

WE learn from the *Athenaeum* that Dr. Trootz, the Belgian Minister of the Interior, who is also Minister of Education, has proposed in the Chamber the foundation of a *Belgica* prize for the promotion of oceanic researches by Belgians, and that the prize shall be allotted at the discretion of the scientific class of the Academy. The sum of 41,000 francs, which will constitute the nucleus of the projected prize, has been obtained by the sale of the *Belgica*, the ship of the Belgian South Polar Expedition, to the Norwegian Government. Lieut. Gerlache, who was the leader of the expedition, suggests, on the other hand, that the capital of 41,000 francs should be put out to interest until the fund amounts to 100,000 francs, and that the interest should then be expended upon grants to Belgian oceanic explorers, and also upon a *Belgica* medal, to be bestowed upon polar explorers of all nations. It is reported that the Minister is now inclined to support Lieut. Gerlache's two suggestions.

A STRIKING example of the improvements which have been made in the mechanical arrangements for the loading of coal from railway trucks into vessels has recently been afforded by a new hydraulic coal hoist which has been erected at the Penarth dock. A steamer arrived in the dock at 8.10 in the morning. After taking in sufficient coal for her boilers she proceeded to load her cargo at 9.15, which was completed at 11.50, the steamer entering and leaving the dock on the same tide. The quantity of coal placed in the vessel was 2333 tons, in two and a half hours, or at the rate of about fifteen tons a minute.

THE next meeting of the International Navigation Congress is to take place at Dusseldorf from June 29 to July 6, 1902. The subjects that will be specially considered are (1) as regards inland navigation; lifts; lifts on inland waterways; the transport of coal. Communications are invited on the construction of reservoir dams; improvements in the mechanical propulsion of vessels; utilisation of water-power at weirs for electric propulsion. (2) Ocean navigation; construction of iron and wooden gates for locks; the use of sea-going lighters; construction and management of graving docks and repairing slips; construction and cost of dredging machinery.

A PROJECT is now under consideration by the municipality of Vienna for disposing of the sewage of the city, which at present is discharged into the Danube. The scheme consists in the application of a method developed by Herr Noebel, of Posen, for the utilisation of the liquid part of the sewage for the double purpose of irrigation and manure. It is intended to convey the sewage in pipes to an extensive plain of poor land which suffers from a lack of water, due to inadequate rainfall, over which it is not to be carried in trenches, as is done in this country, but the surface of the land is to be irrigated by sprinkling the sewage water over it. It is contended that by this system the land will not be over-saturated, as it frequently is on the sewage farms at Berlin and Paris. The system is stated to have been already in use at Posen, with satisfactory results.

PROF. FREDERICK STARR, who for several years has closely studied the physical types of the tribes of southern Mexico, has, says *Science*, just brought his work to a close. Three kinds of work were done—measurement, photography and modelling. In each tribe one hundred men and twenty-five women were measured, fourteen measurements being taken of each individual. Photographic portraits were taken of typical subjects, a front view and a straight profile being made of each. Busts in plaster were made of those who appeared most perfectly to present the racial type, the moulds being made directly upon the subject. During the four seasons over which his work has extended, Prof. Starr has visited twenty-three tribes. While the physical types of the natives formed the chief subject of study, many views were also taken of the scenery, villages, houses, groups of Indians, native industries, &c. The material results of the investigation include measurements from 2850 persons, 1200 or more negatives, varying in size from 8 × 10 inches to 4 × 5, 100 busts in plaster and a large collection of objects—dress, weapons, implements and products—illustrating the ethnography of the region. Several months will be necessary for putting all this material into shape for exhibition and publication.

THE Deutsche Seewarte has published, as an appendix to the August number of the *Annalen der Hydrographie*, a useful collection of storm tables for the Atlantic Ocean. For some years the Seewarte has been collecting and publishing notices of storms, giving, in a very concise form, the time, position and duration, the reading and motion of the barometer (rising or falling) and the various changes of the wind (backing or veering). The results have been arranged in tabular form, in twenty-two districts, according to months and seasons, and grouped under four principal points of the compass. The chief object of the tables is to show at a glance if, on the occurrence of bad weather (when the wind force has reached a fresh gale), there is a prospect of it becoming worse, what the probable further behaviour of the storm will be. The explanatory text contains useful remarks respecting the general distribution and characteristics of storms in different seasons and in various localities of the Atlantic.

AN important publication, just issued by the Department of Revenue and Agriculture of the Government of India, brings together the agricultural statistics of British India and of the Native States, so far as they can be procured, for the five years 1895–6 to 1899–1900. The first thirty pages are explanatory. The bulk of the volume consists of tables of figures, giving the areas of cultivated and uncultivated land; the areas under each crop (the irrigated and not irrigated separately mentioned); the average yield of the principal crops; the number of farm animals, ploughs and carts; the statistics of land revenue assessment, and of transfers of land, for each separate district in the empire. The information will be of the greatest value to those who have the task of developing the resources of the country. The general summary of the acreage described for the year 1899–1900 is as follows:—

	British India, Acres.	Six Native States, Acres.
Total area surveyed	544,858,070	45,952,429
Under forest	65,843,924	3,087,209
Unculturable	135,506,014	11,374,311
Culturable waste	106,404,704	9,765,998
Fallow land	57,163,761	5,452,596
Sown with crops	180,151,093	10,385,927
Irrigated	31,544,056	1,357,463

THE Report on the Observatory Department of the National Physical Laboratory for the year 1900 has been published in the *Proceedings* of the Royal Society. The magnetographs have been in constant operation throughout the year, but the curves have been quite free from any large fluctuations. The mean westerly declination for the entire year was 16° 52'·7. The automatic and tabulated records of the various meteorological instruments have been transmitted, as usual, to the Meteorological Office, to be dealt with in its publications, and special cloud observations have been made each month in connection with the international scheme of balloon ascents. Seismological observations have been regularly made; two noticeable disturbances occurred during the year, on January 20 and October 29. A detailed list of the movements of the seismograph will be published in the Report of the British Association for the present year. As regards experimental work, the observation of distant objects during mist and fog and researches upon atmospheric electricity, referred to in previous reports, have been regularly continued. The list of the various instruments tested is a very long one; we therefore select only a few of the principal cases in which a considerable increase has occurred:—Aneroids and marine barometers (number tested in year 1900), 336 (increase 69); compasses, 963 (increase 559); rain gauges, 1345 (increase

784); clinical thermometers, 20,476 (increase 4456); total number of instruments tested, 27,569 (increase 5518). The principal addition to the staff during the year has been the appointment of Dr. J. A. Harker as an assistant in the Laboratory. Among the different appendices may be mentioned one showing the mean values of the magnetic elements at observatories the publications of which are received.

THE first number has reached us of the "University of Missouri Studies," a publication which it is proposed to issue as irregular intervals as often as work of the required standard it offered by members of that University. The present number consists of "Contributions to a Psychological Theory of Music," by Dr. Max. Meyer, professor of experimental psychology.

PROF. ANGELO ANDRES, writing in the Lombardy *Rendiconti*, discusses the choice of a base line in the so-called "rational" measurement of animals according to which the various dimensions are expressed in terms of one measurement, generally representing the length of the animal. As a result of the considerations brought forward by the author, the distances which best satisfy the requirements in the selection of the base fall, in the case of vertebrate animals, into six groups, according to the particular class of animals considered.

A STUDY of the nummulites of southern Italy has been made by Dr. Giuseppina Gentile, chiefly from observations of specimens in the geological museum of the University of Naples. The examples which the authoress describes, belonging to twelve species and five varieties, come from the Middle and Upper Eocene formations, the former being represented by a prevalence of the forms *N. laevigata, N. lucasana and N. perforata* and the latter strata being characterised similarly by a prevalence of *N. Tchihatcheffi* and *N. Guettardii.* The paper is to appear in the *Atti* of the Naples Academy.

WITH the object of conducting researches in limnology in Italy similar to those instituted in Switzerland by Forel, the Reale Istituto Lombardo appointed in 1896 a committee to investigate the variations of temperature in the lake of Como, and a preliminary report appears in the *Rendiconti* of the Academy, xxxiv. 11. The western limb of the lake is particularly suitable for such observations, on account both of the regularity of its basin and, more especially, on account of the absence of any fluvial current of importance. The vertical distribution of temperature is in conformity with the measurements obtained by Burguières and Forel. In connection with the annual variations, the most remarkable feature (observed in two consecutive years) was the irregular undulation of the curves at depths of twenty and thirty metres, and in particular the appreciable cooling which at these depths occurs in the hottest months. Observations have also been made on the variations of long period, and on the horizontal distribution of temperature across various sections of the lake.

THE *Journal* of the Royal Microscopical Society for August contains the full report of the paper to which we have already alluded, by Mr. J. W. Gordon, on the Abbe diffraction theory, very fully illustrated by a large number of diagrams. The main point of Mr. Gordon's contention is that the diffraction effects seen in the use of Zeiss's *Diffractions Platte* are produced by the diaphragm itself. He maintains that the diffraction theory has virtually been abandoned by Prof. Abbe himself. In the discussion which followed, in which Prof. S. P. Thompson and Mr. Julius Rheinberg took part, and which is also reported in full, the prevalent view appeared to be that while Mr. Gordon had successfully exposed the incorrectness of some of the statements of Naegeli and Schwendener and of other exponents of the theory, he had not succeeded in showing that these errors were the necessary consequences of the theory.

M. BLONDEL concludes his paper on oscillographs and their use in the current number of the *Revue générale des Sciences* with an account of his work on the alternate current arc. The paper contains a number of very interesting oscillograph curves—the first to be published of those taken by Mr. Blondel's double oscillograph—showing the variation of current and potential difference with an alternate current arc between carbons or between carbon and metal. The general characteristics of these curves are now fairly well known, either through the previous papers by M. Blondel or through the exhaustive series of waveforms in Mr. Duddell's paper in the *Journal* of the Institution of Electrical Engineers (vol. xxviii. p. 1). Greater interest attaches, therefore, to the curves showing the effect of an alternating current superimposed on a direct current arc. The form of these curves throws important light on the much-discussed "negative resistance" of the arc. The curves published by M. Blondel lead him to the conclusion that the value of dV/dA is very small, positive for cored and negative for solid carbons. This ratio, the negative value of which, found by Messrs. Frith and Rodgers, gave rise to the controversy alluded to above, is defined by M. Blondel as "the coefficient of stability," which seems to us a very convenient term.

A REPORT by Prof. T. E. Thorpe, C.B., F.R.S., on the work of the Government Laboratory upon the subject of the use of lead compounds in pottery, has been published as a Parliamentary paper. It may be remembered that a detailed report upon the use of lead compounds in the production of pottery glazes and colours was prepared by Profs. Thorpe and Oliver in 1899, and the conclusions were described in these columns (vol. lx. p. 18). Since the publication of that report a large number of further experiments have been made upon lead fritts and upon glazes containing their lead in the form of lead fritt, and a second paper was issued a short time ago. The present paper embodies chemical evidence which Prof. Thorpe has to offer in connection with the special Rules drawn up for potteries as to the use of fritted lead and its degree of insolubility. Fritted lead is a silicate or borosilicate of lead formed when "raw" lead, that is, red lead, white lead or litharge is fused or fluxed with a part or the whole of the silica, or of the silica and the other materials used for the glaze. Potters agree that fritted lead can be substituted for raw lead in every section of pottery manufacture, and it was thought by the Department Committee (1893) on lead poisoning that this would mitigate the evil, then very prevalent. But there are different kinds of fritted lead depending upon the proportions of the materials taken. Some lead fritts appear to be little less soluble in dilute acids than raw lead, and therefore have just as injurious an effect when they find their way into the system of the potter and are dissolved by the gastric juice. Other fritts are nearly insoluble and therefore innocuous. It is to ensure the use of such insoluble, or slightly soluble, fritts that the efforts of the Home Office are now directed. Practical difficulties have, however, arisen as to the standard and tests of solubility, and Prof. Thorpe's report deals chiefly with the objections which have been raised to the proposed Rule on scientific grounds.

DR. R. W. SHUFELDT, in the *American Naturalist*, discusses the osteology and systematic position of the auks and puffins. After reviewing the various arrangements proposed by other writers, the author considers that these birds should form a suborder (= order of most ornithologists), the Alcæ, which is connected, on the one hand, with the plover group through the gulls and their allies, and on the other, through the petrels, with the penguins, loons, grebes and their extinct toothed ally, Hesperornis. In reality, this arrangement is not very different from the one proposed years ago by Dr. Sclater, who placed the auks and loons in a single order (Pygopodes), flanked on the one side by the petrels and on the other by the penguins.

THE July issue of the *American Naturalist* opens with a continuation of Mr. W. H. Wheeler's account of the compound and mixed nests of American ants, the present section dealing with the instances of "social symbiosis." No less than eight different types of this association are recorded, for each of which a special term is adopted. Plesiobiosis, for instance, indicates the cases where ants of two (rarely more) species, which are generally inimical to each other, excavate their galleries in close contact. Xenobiosis, on the other hand, refers to the so-called guest-ants, which maintain independent households among their hosts, with whom they may be on terms of toleration, or even friendship; while Dulosis is applied to cases where one species of ant is kept in slavery by another. The paper teems with interest to students of ant-life.

THE important series of descriptive catalogues recording the collections made by the Royal Indian Marine Survey ship *Investigator* has been enriched by the appearance of "A Descriptive Catalogue of the Indian Deep Sea Crustacea Decapoda Macrura and Anomala." In his preface the author, Major A. Alcock, states that although most of the new species obtained during the dredging cruises of the vessel under his direction have been described in earlier publications, the present volume must not be regarded as a mere reprint of such reports. It contains definitions of the larger groups under which the species are arranged and also valuable tables of distribution, as well as a considerable amount of material prepared by the author as the basis of a larger work on Indian crustaceans. Out of a total of 117 species of Macrura (lobsters, crayfish, shrimps, &c.) obtained during the various cruises, sixty-nine are believed to be peculiar to Indian waters. Most were obtained in less depths—mostly much less—than 1000 fathoms; and out of eleven dredged from deeper water, only five appear to be truly abyssal, several of the others being taken in the net during its ascent. The Anomala present a greater percentage of deep-sea forms, eight out of fifty-two being abyssal types.

DESPITE an unfortunate falling-off in the income, the Report of the Manchester Museum for 1900–1 tells of continued progress of that institution. Owing to the generous presentation of his collection by Mr. P. Schill, which is especially rich in Eastern Holarctic forms, the Manchester series of Lepidoptera now occupies a foremost position among provincial cabinets. The director has also to report the presentation by Mr. R. D. Darbishire of a shell of *Pleurotomaria adansoniana* from Barbados; and the purchase of duplicate shells from the Layard collection has been a most satisfactory investment, the sale of superfluous specimens having repaid the entire cost, while more than 2000 examples have been added to the Museum series. The herbarium has also been largely increased. Neither has the exhibition series been neglected, the director calling especial attention to the display of the various groups of worms, as well as to the dissections and drawings illustrating the anatomy of molluscs.

WE have much pleasure in congratulating the Field Naturalists' Club of Victoria on its "coming of age," an event which was duly celebrated in Melbourne on June 25. In calling attention to the present condition of the Club, the committee were able to report, in spite of increased expenditure, a slight improvement in the finances and also an increase in the roll of members. During the year the Club has called attention to the destruction of various species of "wattle" (*Acacia*), and also to the spread of the water-hyacinth and iris—it is hoped with good results. Among other papers, the July issue of the *Victorian Naturalist* contains one describing the curious incrustations formed on roots in the littoral sand-dunes of certain districts. The theory that these are formed by the action of vegetable acids on the lime contained in the sand is confirmed. By the decay of the contained root and the percolation of calcareous matter these incrustations may become solid throughout.

THE occurrence of chrysoberyl in the gneiss of Manhattan Island, New York City, is recorded in a pamphlet published by Mr. W. G. Levison (New York, 1901).

AN article in the *Pioneer Mail* of July 5, 1901, deals with the important question of artesian wells for India, and it is urged that the Imperial Government should undertake a series of borings. Mr. Griesbach, the Director of the Geological Survey of India, has suggested that a search for artesian water might be made in the flat country enclosed by Mahi Kantha on one side and Kathiawar on the other in Gujerat proper. If successful the wells would be useful in the northern division of Bombay.

A PRELIMINARY report on the Cape Nome gold region on the south-western coast of Alaska has been prepared for the United States Geological Survey (1900) by Mr. F. C. Schrader and Mr. A. H. Brooks. In this region the bed-rock consists of altered limestones, mica schists and gneisses, and above it are various gravels forming beaches and terraces, which occur in the gulches (creeks) and valleys and also over the tundra. It is remarked that the gulch and beach placers are extraordinarily rich in gold, and the metal is also known to occur in the bars of the larger rivers and in the tundra. No bed-rock mining has been done, but as the gravels and gold are largely of local origin, workable veins may eventually be found. The authors observe that the staking of new claims "is probably nearly a thing of the past, yet those having capital to invest will undoubtedly find plenty of claims for sale." They add, "it would be very wise for all inexperienced newcomers to save money for the return passage."

A NEW scientific journal, the *Allgemeine Naturforscher-Zeitung*, will be published in Berlin early in October. The prospectus states that the journal will be "die erste naturwissenschaftliche Zeitung der Welt."

A SECOND edition of the second report of the United States Board on Geographic Names has been received, and with the exception of a few minor corrections it is the same as the original edition of May, 1900. The general policy of the Board has been to adopt the name which is in common local use at present, but local usage has been neglected in some cases in order to effect reforms in nomenclature. Among these departures approved by the Board are the following:—the avoidance, so far as practicable, of the possessive form of names; the omission of the final "h" in the termination "burgh"; the abbreviation of "borough" to "boro"; the spelling of the word "centre" as "center"; discontinuance of the use of hyphens in connecting parts of names; the simplification of names consisting of more than one word by their combination into one word; the avoidance of the use of diacritic characters; the omission of the words "city" and "town" as parts of names. Evidently these principles have their limitations, and the Board recognises the practical impossibility of inducing English people to speak of Germany as Deutschland, Turin as Torino, or The Hague as 's Gravenhage. It is suggested, however, that the adoption of the home name "is a reform to which we may look forward and work toward, and which may be attained in the future." Each name must evidently be considered separately, and the Board exists to do this and to decide what name shall be adopted. The present report contains all decisions rendered by the Board from its creation to April, 1900.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus patas*) from West Africa, presented by Mr. U. R. Noble; two Bonnet Monkeys (*Macacus sinicus*) from India, presented respectively by Mrs. Noble and Miss Weil; two Ring-tailed Coatis (*Nasua rufa*) from South America, presented respectively by Mr. Charles North and Mr. E. F. Johnston; two White-tailed Gnus (*Connochaetes gnu*) from South Africa, presented by Mr. C. D. Rudd; an Osprey (*Pandion haliaetus*) captured at sea, presented by Commander H. Strong; a Toco Toucan (*Ramphastos toco*) from Guiana, a Red-billed Toucan (*Ramphastos erythrorhynchus*) from Cayenne, a Hutchin's Goose (*Bernicla hutchinsi*) from Arctic America, presented by H.E. Sir W. J. Sendall, G.C.M.G.; two Infernal Snakes (*Boodon infernalis*), six Rufescent Snakes (*Leptodira hotambaeia*), six Rhomb-marked Snakes (*Trimerorhinus rhombeatus*), five Crossed Snakes (*Psammophis crucifer*), two Rough-keeled Snakes (*Dasypeltis scabra*) from South Africa, presented by Mr. A. W. Guthrie; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Miss Wilson; an Eyed Lizard (*Lacerta ocellata*), a Tessellated Snake (*Tropidonotus tessellatus*), South European, presented by the Rev. F. J. Jervis-Smith, F.R.S.; a Brindled Gnu (*Connochaetes taurina*) from East Africa, purchased.

OUR ASTRONOMICAL COLUMN.

NOVA PERSEI.—A telegram from Kiel announces that photographs of Nova Persei, taken on August 19 and 20 by MM. Flammarion and Antoniadi, show a nebulous aureola having a definite sharp outline.

PERIOD OF MIRA CETI.—Prof. A. A. Nijland finds from a series of thirty-nine observations of this long-period variable during the interval July 17 to September 11, 1900, that the maximum occurred last year on August 3. As will be seen from the table below, this brings the period back to the short value of 1897. (*Astronomische Nachrichten*, Bd. 156, No. 3733.)

Observed maximum.	Predicted (Chandler III.).	Magnitude.	Period.
1897 Jan. 11	1896 Dec. 12	3·70	
			319 days
1897 Nov. 26	1897 Nov. 9	3·24	
			312
1898 Oct. 4	1898 Oct. 6	2·91	
			350
1899 Sept. 19	1899 Sept. 3	3·75	
			318
1900 Aug. 3	1900 Aug. 1	3·35	

THE CAPE OBSERVATORY.—The annual report to the Admiralty has recently been issued by Sir David Gill, and summarises the work done at the institution during the year 1900.

The new transit observatory is now satisfactorily erected. It is of sheet steel, having triple sides, thus forming a double series of ventilating shafts, arranged so as to carry off all heated air by convection and deliver it by funnels 13 feet distant from the observing shutter; this latter is 6 feet wide, formed by the two halves of the building sliding apart.

The upper part of the structure is semicylindrical, its axis coinciding with that of the transit circle. It is hoped that this symmetry between building and instrument will eliminate abnormal refractions. The double-chambered walls have made it possible to attain practical equality between the external and internal temperatures.

Transit Circle.—Much of the transit circle work has consisted of a thorough investigation of the influence of "star magnitude" on the observers' personal equations. The results are given in detail, and indicate that, while there is considerable range in magnitude personality for different observers, every observer records the time of transit of a faint star later than that of a bright one, and also, as a rule, this personality is greater "per magnitude" for faint than for bright stars. Another somewhat unexpected fact brought out by the investigation is that the difference of personality remains nearly the same for stars of very different declination.

Heliometer.—Regular observations of all oppositions of major planets have been continued—of these fifty-three related to Jupiter, forty to Saturn, forty-four to Uranus and sixty-six to Neptune. Observations were also made of the conjunction of Jupiter and β Scorpii, and of the distances of the cusps of the partially eclipsed sun on November 22, 1900.

McClean Equatorial.—The 24-inch photographic objective has been refigured and forwarded to the Cape from Dublin. The 18-inch visual telescope has been employed in the observation of double stars, thirty-one previously unrecorded pairs being found, nine of which are naked-eye stars.

In consequence of the absorption of the three heavy flint prisms belonging to the "line of sight," spectrograph they have been replaced by four of lighter glass giving the same total deviation. Mr. McClean, who is providing these, has also generously given an order to Messrs. Zeiss for a second objective prism of 24 inches aperture and 10° refracting angle.

Physical Laboratory.—Investigations have been in progress by Mr. Lunt dealing with the spectra of oxygen, silicon, aluminium, boron and sulphur, and provision is being made for a further study of the spectra of various gases.

Astrographic Charts and Catalogue.—One hundred and three triple image chart plates have been passed, bringing up the total to 362. For the revision catalogue, 172 plates have been taken. During the year, 124 catalogue plates, containing 71,655 stars, have been completely measured in both coordinates in reversed positions of plate.

South African Survey.—This has been pushed rapidly forward in Rhodesia, the party reaching latitude 16° 30′ S., and they expected to reach the Zambesi by the end of July. The operations for the Anglo-German Boundary Survey are also in steady progress. It is hoped that arrangements will soon be possible for the extension of the survey through the international territories north of Rhodesia, thus bringing the long-wished-for African arc of meridian nearer to practical realisation.

OBSERVATION OF COMET *a* (1901).—Mr. J. Cresswell, writing from a mining camp near the centre of Borneo, sends a drawing of this comet, which was visible there on May 7–12. He says:—"It was very bright, and had two tails which on May 10 were 29½° apart and on May 12 35° apart. The lower tail was less bright than the upper. I looked for it during the solar eclipse, but did not see it." Further observations were prevented by cloud.

THE AUGUST METEORS OF 1901.

THE weather was tolerably clear near the time of the maximum and enabled the shower to be pretty well observed. On August 10, 11 and 12, or on one or two of those nights, a considerable number of meteors were recorded at various places where the clearness of the sky permitted observation. The maximum appears to have occurred rather later than usual, for the greatest number of meteors displayed themselves on Tuesday morning, August 13, but the state of the sky did not allow the progress of the display to be fully observed during its rise, culmination and fall.

The first marked indication of the Perseids as a definite shower became apparent on July 21, when the writer at Bristol recorded five swift streak-leaving meteors from a radiant at $23° + 52°$, but two of them were imperfectly seen and their directions could be only roughly noted, so that the resulting radiant was not very satisfactory, though there could be no doubt of its actual existence either at or very near to the position assigned.

Between July 21 and August 10 the development of the shower could not be fully traced, owing to moonlight or cloudy weather. On August 10 the display was moderately rich. There was no special activity on the part of the Perseids, but the minor showers of the period were in prominent evidence and provided meteors as fast as the observer found it convenient to record them. Between about 9h. 30m. and 15h. the total number of meteors seen by the writer at Bristol was 102, but nearly half of the time mentioned was consumed in registering paths. While the observer's attention was, in this manner, diverted from the sky, a large number of meteors must have eluded notice; of the 102 seen 55 were Perseids.

On August 11 the sky was clear until after midnight, and between 9h. 30m. and 12h. 30m., 72 meteors were noticed, of which 49 were Perseids. As compared with the previous night the Perseids had increased, while the other meteors exhibited a marked decrease. Clouds prevented further observation at 12h. 30m.

On August 12 the sky was overcast, but between 14h. and 14h. 30m. there was a break along the east and south-east horizon, through which a few of the stars could be seen. Meteors were numerous, and it was considered that with a clear sky the display would have been unusually fine.

A few cloudy nights intervened, but on August 15 and 16 observations were secured during clear intervals. The Perseid shower was still actively in play, and supplied about one-third of the aggregate number of meteors visible. On August 18 the sky was watched between 9h. 30m. and 14h. 15m., but meteors, generally, were extremely rare. The Perseid shower furnished eight paths, so that the display was still well defined. On August 19, observations were made between 9h. 30m. and 15h., and 40 meteors were seen, of which 3 only were Perseids, so that the stream had become nearly exhausted. The radiant point was determined from several well-observed paths on each night, and its easterly position as compared with its place on August 10 and 11 was strikingly evident. Between July 21 and August 18, its R.A. differed to the extent of 32°, as the following figures will prove:—

July 21	... $23° + 52°$	...	5 meteors
Aug. 10	... $44 + 58$	...	55 ,,
11	... $45 + 58$	...	49 ,,
15	... $51 + 58$	...	6 ,,
16	... $53 + 58$	...	5 ,,
18	... $55 + 59$	...	8 ,,

The Perseids furnished some brilliant specimens, but there was only one fireball seen by the writer. This appeared at 11h. 2m. on August 11, and lit up the south-eastern sky with a lightning-like flash. It was seen also at Birmingham and Yeovil, and its height is given in the table. The largest meteors recorded at Bristol were as below:—

	h.	m.		From	To	
Aug. 10 ...	12	47	♃	$331\frac{1}{2}° + 6\frac{1}{2}°$ ...	$324\frac{1}{2}° - 6\frac{1}{4}°$ ...	swift stk.
...	13	0	♃	$33 - 4$ ...	$32 - 12$ ...	v. swift stk.
...	13	$17\frac{1}{2}$	>♃	$333 + 60$ ...	$302 + 45\frac{1}{2}$ ...	v. swift stk.
...	13	33	1	$62 + 22\frac{1}{2}$ ...	$66 + 11\frac{1}{2}$ ...	v. v. slow.
Aug. 11 ...	11	2	2×♀	$353\frac{1}{2} + 7$ ...	$343 - 14$ ...	v. swift stk.
...	11	34	♃	$43 + 79$ ...	$232 + 73$ ...	sw. b. stk.
...	11	56	♀	$120 + 74$ ...	$160 + 65$ ...	sw. stk.
12 ...	14	4	♃	$46 - 5$ ...	$46 - 15$ ...	sw. stk.
19 ...	14	5	♃	$322 + 48\frac{1}{2}$ ...	$338\frac{1}{2} + 41$ ...	v. slow train.

Four meteors seen on August 10 were also recorded by Prof. A. S. Herschel at Slough, and their real paths have been determined. Their heights, &c., are included in the following table, in which are also given the results for the fireball of August 11, which left a streak for about a minute amongst the stars of Aquarius. It must have been a magnificent object from the English Channel:—

	h. m.	mags.	Height at first miles.	Height at end miles.	Path miles.	Velocity per sec. miles.	Radiant
Aug. 10 ...	10 41	3 – 2	91	72	20	24	$278° + 67°$
	12 0	1	76	51	36	50	$44 + 58\frac{1}{2}$
	12 16	2 – 1	69	50	27	39	$42 + 57$
	12 19	3 – 2	72	60	33	25	$149 + 60$
Aug. 11 ...	11 2	2 × ♀	95	56	64	...	$45 + 58$

The latter object began over the channel at a point about 25 miles W. of Dieppe, and ended a little W. of Havre on the French coast. It would be interesting to hear further descriptions of it from the channel and from the north region of France.

Reports are coming in from various observers, and show that the display was quite up to, if it did not exceed, the average. Mr. D. E. Packer, writing from Birmingham, says:—"On Saturday night, August 10, several hundreds of meteors were observed here in a four-hours' watch, commencing at 10 p.m. On Sunday, August 11, during the same period of time the number nearly reached a thousand. At 11 p.m. a magnificent fireball burst over the southern part of the sky, lighting up the heavens with a full moon radiance and leaving a brilliant streak of light which persisted for some little time." A correspondent of the *Nottingham Daily Guardian* says:—"On August 10 we had a splendid display of the meteors. The night proved to be the brightest and clearest I ever remember to have seen, and at about 10 o'clock meteors in great numbers were to be seen flitting across the heavens from north-east to south-west. On Sunday night, August 11, the display was repeated with even greater brilliance and frequency and with more variation, the sky being again very clear."

These descriptions may possibly convey a somewhat exaggerated idea of the character of the shower this year, but they sufficiently prove that the event was a conspicuous one and well worth the attention given to it.

As observed at Bristol the radiant point was pretty definite, for an area of about 3 degrees would include very nearly all the tracks directed from it on August 10 and 11. With reference to the minor showers, there were a considerable number visible, though they were very feeble. A few degrees south of the head of Draco and at the point $269° + 47°$, there was a radiant of bright-trained, slow-moving meteors, while east of ζ Persei at $63° + 30°$ there was a radiant of very swift streak-leaving meteors. There were other well defined showers from $290° + 53°$, $312° + 13°$ and $333° + 72°$.

W. F. DENNING.

Mr. W. E. Rolston sends the following account of observations made by him:—

"I commenced my observations at Birmingham at 10.45 p.m. on the night of August 11 and continued them till 12.48 a.m. on the morning of August 12, when a bank of clouds rising from the N.E. stopped further observations. For this period, of 2 hours 3 minutes, I counted 143 meteors, which appeared to have their origin in the region of Perseus, and 17 others having various origins. During this time a very clear sky obtained, rendering short and faint trails easily visible. All the observations were visual, and, as I happened to have exhausted my stock of plates, I was unable to attempt the securing of "trail" photographs. Several of the Perseids were remarkable either for their brightness, or else for the length of time their trails were visible after the nucleus had either disappeared below my horizon—of surrounding houses—or had died away. Observations on these, including the times of their appearance, are given in the appended table.

"From the 143 observations made, I deduced that the radiant point of these meteors is situated about the point whose coordinates are:—Decl. 58° N., R.A. 2h. 35m.

G.M.T. of appearance. (h. m.)	Remarks.
11 7	Remarkable for a very bright nucleus, and a vivid trail which remained visible *for* 53–55 *seconds;* first appeared in the region of κ Andromedæ (alt. about 60°), and travelled between Aquila and Delphinus to about alt. 25°, when it disappeared behind a housetop. The trail had a bluish-white and shimmering appearance.
11 14	Appeared in region of δ Cassiopiæ; was very bright, and trail lasted for 7 seconds.
11 35	Appeared in region of δ Cygni and travelled through Lyra, leaving a bright trail which lasted for 9 seconds.
11 53	Appeared in region of α Persei and travelled towards Aries; was very short, but very bright; evidently the greater component of its motion was in the line of sight.
11 55	Appeared in region of 33 Cygni and travelled S.W. through Lyra; very bright, and left a bright trail which lasted about 8 seconds.
12 5	Very bright and short; left bright trail which was, as nearly as I could judge, exactly parallel to a line joining β and γ Arietis, and near to them.
12 10	Very bright, leaving a good trail from Cassiopeia, half way between β Pegasi and ε Cygni.
12 15	A very bright meteor which "occulted" α Andromedæ and then travelled in the direction of the group 59, 57 and 55 Pegasi.

"In addition to the above, I remarked one of the extra 17—not a Perseid—which at 11.27 appeared at about the middle of The Great Square and travelled right through the zenith, disappearing near Corona and leaving behind it a remarkable red shimmering trail which lasted for 4 or 5 seconds.

"The above times given for the duration of trails were obtained by counting seconds from judgment, not by a watch. The observations were made whilst lying on my back, so that nearly the whole of the sky above the available horizon was observed."

SAND WAVES IN TIDAL CURRENTS.[1]

THE sand waves dealt with in this paper are not the well-known "current mark," or ripple mark of rivers, but the larger sort, first scientifically described by Prof. Osborne Reynolds. These larger sand waves are the normal production of a swift current when adequately supplied with sand. The supposed condition of "uniform drift" (the current picking up as much sand as it drops, and therefore neither silting nor scouring) is really so unstable that, when the current becomes sufficiently swift to hold sand in eddying suspension, it passes almost suddenly into wave motion, uniform drift being replaced by alternate silt and scour, giving ridges and furrows of sand which travel down stream. The material of the ridges is constantly being picked up by the current from the weather slopes, and deposited upon the lee slopes. Some explanation of the process was given in NATURE (vol. lxiii. p. 623, April 25) in the abstract of another paper by the author;[2] this is further elaborated in the paper now before us, which contains also details of the observations and measurements carried out during the year 1900, which have not hitherto been published.

The amplitude of the tidal sand waves is obviously limited by the depth of water, and it follows that as the tide ebbs off sand-banks, it tends to obliterate the ridges, leaving the banks with the smoothed surface which is familiar. Sometimes pools are left below the general level of the smoothed surface (Fig. 1). These have a steep and a gentle side, the former the lee slope of one ridge, the latter the weather slope of the next ridge. They are, in fact, homologous with the pits, called Fuljes, in sandy deserts.

FIG. 1.—A chain of pools, Annat Sand, Montrose.

Where the conditions are such that the tide covers and leaves the banks gently, though running strongly when the water is deep upon them, the banks dry out with their wave surface almost perfectly preserved. The required conditions were found by the author in the tidal basins with narrow entrances at Barmouth and Aberdovey, North Wales, at Findhorn and Montrose, N.B., and at the Dun Sands, on the Severn (Fig. 2), which are protected from the tide until well submerged by a rocky shoal, which juts out from the left bank of the river.

The observed wave-length or distance from ridge to ridge varied from 3 feet 6 inches to 54 feet. The smallest of these measurements was unusual. From 12 to 24 feet wave-lengths were common. The steepest ridges had a wave-length 13·39 times as great as their height. In the model estuaries of Prof. Osborne Reynolds the wave-length was twelve times the amplitude.

FIG. 2.—Interpenetrating ridges on the Dun Sands.

Fig. 3 shows the orderly march of the ridges upon a portion of a sand-bank in the estuary of the Dovey, which the author pegged out for purposes of measurement with stakes driven into the sand to a depth of about 3 feet. There were five transverse rows of stakes 15 feet from row to row, and in each transverse row the distance from stake to stake was 20 feet. This permitted the exact measurement of the position of five wave-fronts along four sections. String stretched from stake to stake at the two sides of the plot served as datum lines and enabled amplitude and mean-sand-level to be taken with tolerable accuracy along two sections. Measurements were made once a day when the sands were dry. From June 2 to 5, 1900, the tides were diminishing after springs, and the average amplitude of the ridges diminished from 6″·34 to 3″·71 with no perceptible change of mean sand-level. The average wave-length in the same time only diminished from 14′ 3″·7 to 13′ 6″·6, and the regularity of the wave-lengths improved, thus:—

	Per cent. of mean L.
On June 1, av. diff. of successive Ls.	= 13·4
,, 2 ,, ,,	= 11·4
,, 3 ,, ,,	= 10·7
,, 4 ,, ,,	= 4·4
,, 5 ,, ,,	= 6·6

On June 5 the tidal current appeared to have fallen below some critical velocity, and suddenly to have lost control of the wave system. This is shown by the following table of the average advance of the ridges, which was:—

From June 1 to June 2 ...	38″·07
,, ,, 2 ,, ,, 3 ...	29″·75
,, ,, 3 ,, ,, 4 ...	30″·57
,, ,, 4 ,, ,, 5 ...	1″·4

During neap tides the sands of the plot were almost smooth, and such undulations as could be seen on the surface were irregular and ill-defined. During the subsequent increase of tides, however, the plot emerged one day all covered with sharply defined ridges, which grew daily in height, and also (by elimination of some of the ridges) in length. On June 15 the average amplitude was 9″·71, with an average wave-length of 11′ 9″. The increase of wave-length appears to take place by the obliteration of certain ridges which find themselves unfavourably placed owing to the too great growth of the ridge on

[1] Abstract of a paper by Dr. Vaughan Cornish, read before the Royal Geographical Society, June 10, and published in the *Geographical Journal*, August 1901.

[2] "On the Formation of Wave-surfaces in Sand," *Scottish Geographical Magazine*, vol. xvii., January 1901.

the weather side. Thus the increase of amplitude is a steady process, whereas the increase of the wave-length (if determined by measurement along one or two sections of a few ridges) takes place *per saltum*, or, as Dalton might have said, in "multiple proportion."

It is pointed out that the tidal sand ridges, by their size, orientation, and lateral extension, afford an admirable means of mapping the tidal currents in those estuaries in which circumstances secure their preservation on the sand-banks visible above low-water mark.

Between the date of the writing and the publication of this paper the author observed in Canada the formation of long trains of waves of snow, by a process similar to that which creates these sand waves. They are distinct altogether from the ripples of drifted granular snow, which were also observed.

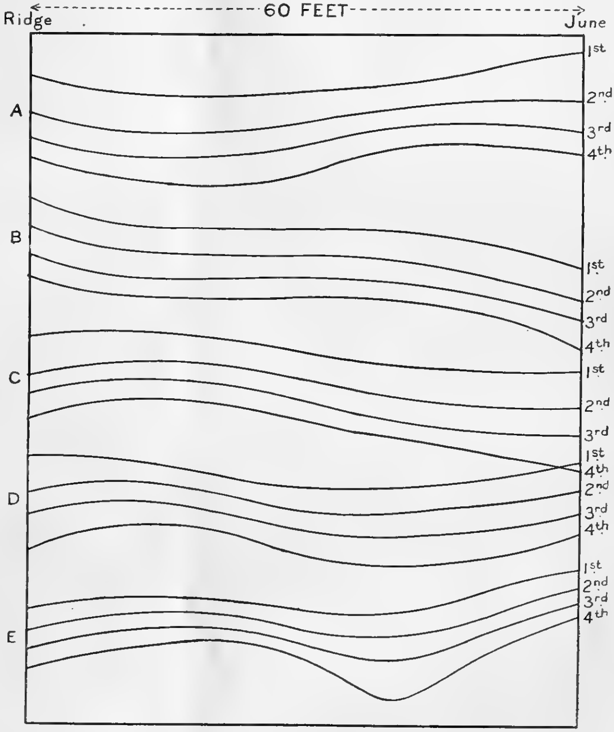

FIG. 3.—Plan of five sand ridges showing positions on four succeeding days, Dovey Estuary. Scale, 1 inch = 16 feet.

WOAD AS A BLUE DYE.[1]

MR. E. CORDER[2] has so thoroughly gone into the matter of East Anglian woad culture and preparation that the present remarks must be regarded as quite supplemental to his paper, having been, in fact, inspired by it. Frequent visits have been made to the Parson Drove Woad Mill, and a long series of experiments conducted before the blue colour, the indigo in fact, in this woad could be demonstrated. Curiously enough, the subject has engaged the attention of Prof. Beyerinck, of Delft, and by his help the presence of indigo was easily shown in the fresh plant from Parson Drove. The blue colour of woad is indigo—the same substance chemically as that obtained from *Indigofera tinctoria* and *Polygonum tinctoria*. There is this great difference however: in the last named plants it exists in a form which is easily extractable, whereas in woad it exists in a condition which is the very reverse.

In 1855, Dr. E. Schunck, in an exhaustive paper on the chemistry of woad, drew attention to the fact that indigo did not exist as ready formed indigo-white in this plant. He showed that the glucoside indican was the form from which indigo-white was produced by oxidation. In 1877, M. Alvarez attributed the formation of indigo to the action of bacteria, but in 1898 Bréaudat demonstrated that microbic life was not necessary.

Marchlewski and Radcliffe consider indican consists of sugar and a very unstable substance called indoxyl. Prof. M. W. Beyerinck holds the view that the indigo producing plants may be divided into two groups, in one of which this substance exists as indican (*Indigofera tinctoria* and *Polygonum tinctoria*), while in the other (of which woad, *Isatis tinctoria*, is the type) it exists as indoxyl. More recently, however, Beyerinck has come to the conclusion that even indoxyl does not exist ready formed in woad, but that it exists as a "loose compound" isatan, which by an enzyme isatase also present in woad is easily decomposed into indoxyl.

Be this as it may, it is not difficult to extract indigo blue from fresh woad leaves by the process given by Beyerinck. This consists in packing fresh woad leaves into a stoppered bottle and filling the bottle entirely with boiling water, inserting the stopper so that no air-bubble is left between it and the top of the water; after a few hours the infusion will be found of a pale yellow colour, having, when cold, a green fluorescence. If an alkali be added to this infusion and air blown through it, indigo blue is precipitated on the further addition of an acid. Woollen articles dipped into this alkalised infusion become, on exposure to the atmosphere, a pale azure blue. This change, however, takes place far more rapidly if they be dipped into acidulated water. The indigo thus obtained is, however, very apt to contain impurities; notably, to pass into a condition known as indigo-brown, in which an insoluble black-brown substance is formed which is useless to the dyer and cannot be reconverted into indigo blue. During the unsettled state of Europe towards the end of the eighteenth and beginning of the nineteenth century, numerous attempts were made to manufacture indigo directly from woad; prizes were offered by various Governments for the attainment of this object in order that the use of foreign indigo might be obviated, as it could only be obtained with difficulty. None of these processes were ever practically successful. Many of them were entirely theoretical. Some sought to obtain indigo by macerating fresh woad leaves in cold water, others in warm water, others by infusing them in boiling water and subsequently washing with cold.

To demonstrate the presence of indigo in the woad leaf, the process of Dr. Hans Molisch is the best. This consists in keeping the fresh leaves in a wide-mouth stoppered bottle, filled with gaseous ammonia for twenty-four hours, and then dissolving out the chlorophyll by immersing the leaves for a like period in absolute alcohol. Sections show that the indigo is confined to those tissues which contain chlorophyll, and that the hairs,

[1] Abridged from a paper by Dr. C. B. Plowright, in the *Transactions* of the Norfolk and Norwich Naturalists' Society, vol. vii. 1900–1901.

[2] Corder, E. *Trans.* Norfolk and Norwich Nat. Soc., 1890, vol. v. p. 144.

cuticular cells (excepting the guard cells of the stomata) and fibro-vascular bundles are free from it. When the chlorophyll has been thus extracted, the leaves have a blue colour of greater or less depth according to the amount of indigo they contain.

Although the extraction of indigo is so difficult and unsatisfactory a process, yet woad has been used as a blue dye from remote antiquity. Pliny refers to it as having been used to stain chalk blue for the adulteration of indigo, which was then a pigment of great rarity, as it had to be imported by the "overland route" from India.

The first printed reference to woad as a blue dye occurs in Ruellius ("De Natura Stirpium," 1536), who remarks in words of which the following is a translation :—"They crush the green plant in mills, so as to expel the vegetable juices, then when the moisture has been removed they make the woad up into large balls, and these they allow to lie on the floor and decay till they fall into ashes (dust). In many places they call woad 'pastel,' from the loaf-like shape into which the woad balls are made up. They heat (the dust of) these balls in vats, in dyers' shops and dip woollen cloths and skins therein, that they may absorb the blue colour. The blue scum floating on the surface, which the vats throw up when warming on the fire, our dyers call indigo; this they dry for the use of painters."

In 1555 Crolach published his small book on woad and its culture and preparation, from which it appears that Thuringia, one of the great woad producing districts of Europe, was already beginning to feel the effect of the introduction of indigo into Western Europe by the Cape route. A century later this was more pronounced, judging from what Wedelius says. His account of the woad industry is very good; so much so that Ray, the first professor of botany at Cambridge, copies it almost verbatim with due acknowledgment, which in its turn was copied and translated by the author of the English edition of Tournefort's "Herbal." The latter tells us, "the ground, which is plow'd in *Autumn*, must be left all *Winter* to be soak'd by the rain, till *the Purification of Our Lady*. After *Lady Day*, when the air is somewhat softer and milder, it is proper to sow it, and your end will be better answer'd if you sprinkle a little snow over it, and take care that you do not sow it too thick . . . . and after *Whitsuntide* you must weed all other herbs from it. After *St. John's Day* in the Beginning of Harvest it is ripe." It is interesting to add that the wadmen of the present day say that, "no wad should be gathered after Martimas Day" (November 15). Wedelius was essentially a chemist, and the main object of his book was to show that ammonia was produced from plants. He showed that ammonia was given off in large quantities during the couching of woad, and he also argued on theoretical grounds that woad contained sulphur, in both of which assertions he was correct. He tells us, as early as 1577 a decree was made at Frankfort to prevent the fraudulent and injurious substitution of indigo for woad, and on April 21, 1654, at Ratisbon, an edict was promulgated inflicting the penalty of confiscation against the further importation of indigo. The days of woad as a dye were, however, rapidly drawing to an end, and yet, paradoxical as it may seem, the dyers of the "greater dye" could not do without it. At this time no other equally good method was known by which indigo could be dissolved and used for dyeing. We find woad culture an important industry during the seventeenth and eighteenth centuries; accounts are to be found in the contemporary agricultural writers—Ellis, Trowell, Miller and Young. It was mostly carried on by itinerant "wadmen," who, with their families, travelled from place to place, growing the woad on newly broken up pasture land for which very high rents were paid. These gangs built their huts and wad mills with the sods from off the land, and were brought up to the industry from their childhood. They seldom stayed more than two or three seasons in the same spot, moving to a fresh location as soon as the soil became exhausted. Abroad Schreber's monograph, published in 1752, gives a very complete account, not only of the culture, but of the history of the subject, as well as copious extracts from the more important writers on the subject, with copies of the various proclamations, edicts, &c. In the appendix to this volume a German translation is given from Hellot's chapter on dyeing wool with indigo and woad. This book (Hellot's) was subsequently translated into English, anonymously. Under the "greater dye" or dyeing "colours in grain," it gives the *modus operandi* of working a woad or pastel vat, which was the best then known way of dyeing with indigo. The directions are sufficiently quaint; for instance, the writer begins by saying, "Your copper cauldron should be placed as near as possible to the vat and then filled with pond water: if the water be not sufficiently putrid you put in a handful of hay. When the copper is full the fire should be lighted under it at three o'clock in the morning." Then again, for every ball of pastel you throw in a full measure of *ware* (slaked lime), and sundry mysterious stirrings and coverings are enjoined, until the vat has "come to." When the indigo is put into it, there follow more stirrings and additions of ware, until the vat is ready for the "overture," or first piece of stuff to be dyed. "Towards the latter end of the week you dye the light blues, and on Saturday night, in order to preserve it 'till Monday, you *garnish* with a little more ware than on the day preceding." On Monday morning the vat was reheated, fresh indigo added to replace that which had been taken out by articles dyed during the preceding week, while bran and lime were added in the proper proportions. In point of fact a woad vat, once started, was kept going for many weeks or months, adding the indigo from time to time as required, as well as the requisite proportion of bran (sharps) and slaked lime (ware). The whole process was an exceedingly delicate one; if the lime was deficient the vat became putrid, if used too freely the vat "got the kick" and did not work at all; this was also the case if the proper temperature was not maintained.

What really takes place in a woad vat is concisely this :—Indigo blue is a very insoluble substance; it will not dissolve in any of the ordinary solvents, such as hot or cold water, dilute acids, alkalies, alcohol, ether, chloroform, &c. Hence it is a very fast dye if it can only be made to attach itself to a fabric. In order that this may be done, it is necessary to dissolve it; but, as we have seen, none of the ordinary solvents will do this. In the woad vat the chemical composition of the insoluble indigo-blue is altered; it is, as chemists say, reduced to indigo-white; now indigo-white is soluble in weak alkaline solution, hence the use of the slaked lime. If a skein of wool be dipped into a vat containing indigo-white in this state, the solution soaks into the tissues of the wool fibres; when the wool is taken out and exposed to the air, the oxygen unites with the reduced indigo and the skein passes from a greenish-yellow to a deep blue, the insoluble indigo-blue being thus formed and the fabric dyed in such a way that no mordant is required. The chemical changes which take place in the woad vat when once started are, that the starch of the bran is converted into grape sugar, which becomes lactic acid. The lactic acid becomes butyric acid, and in so doing nascent hydrogen is liberated, which reduces the indigo to indigo-white. Indigo is soluble in strong sulphuric acid, and there are other processes by which it can be reduced; but the above is the rationale of the woad vat, which has held its own from the time when the mediæval dyers added a little indigo to the vat to improve the colour of the blue down to this present time. It is an expensive, awkward and difficult process, but it has this one advantage—the colour produced is extremely durable. In actual practice a little madder is added; this is done, the dyers say, "to kill the green" in the indigo.

Woad was used long before indigo came into Europe, not as a solvent, but as a dye *per se*. Woad contains no indigo ready formed; not the slightest trace of any blue colour can be detected in it. With water it forms a dark brown mixture, which colours woollen fabrics olive-green. In order to dye with woad, all that is necessary is to pour boiling water on the woad and keep it in a well-covered vessel for fifteen or twenty hours at a temperature of about 110° to 140° F., not going above 150° or letting it fall below 100°. In about thirteen to fourteen hours bubbles of gas begin to rise; a very small quantity of slaked lime should now be added, and in a few hours woollen articles allowed to remain in it for an hour or two change from yellow to blue as they are taken out and exposed to the air. When the vat is in full working order the liquid is of an olive-brown colour, on the surface of which darker veins appear which change their position, slowly moving, appearing and disappearing spontaneously. The froth which at this time gathers on the surface of the vat is blue from the indigo precipitated by contact with the atmosphere. This constitutes the *caeruleum spumam* Ruellius speaks of as being dried and sold to the painters. It was also the "flowers of the woad" which the dyers of Coventry were accused of skimming off the woad vats in which they dyed their customers' goods and added to those vats in which they dyed their own. It is interesting to notice that, if a skein of wool be suspended in a small experimental vat in good working order, it is the upper part of the skein nearest the surface which takes the deepest colour, and next to it, as one would have imagined, the lower part nearest the sediment at the bottom. This blue scum was the probable source, not only of the woad blue which Pliny speaks of as being used in his time to stain chalk with for the adulteration of indigo, but also of the "ancient Briton" pigment, of which we hear so much and know so little. Cæsar and Pomponious Mela speak of our ancestors staining their bodies blue; it is difficult to understand how they could dye their skin blue, but it is easy to see how they could have smeared themselves with woad-blue mixed with oil or grease. Herodian, however, throws a little more light on the subject when he tells us that "they mark their bodies with various figures of all kinds of animals, which is the reason they wear no clothes, for fear of hiding these figures." The use of indigo for tattooing is still common among our soldiers and sailors.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. J. T. JENKINS has been appointed lecturer in biology and geology at the Hartley College, Southampton, and Mr. J. D. Coates assistant lecturer in physics and electrical engineering.

MISS ELEANOR ORMEROD, the well-known authority on agricultural entomology, lately deceased, bequeathed the sum of 5000*l*. to the University of Edinburgh. Miss Ormerod was an examiner in entomology for the University, and received from them last year the degree of LL.D.

THE councils of English Counties and County Boroughs expend upon scholarships a large amount of the money available for technical education. A report upon the scholarship schemes adopted by local authorities appears in the *Record* of Technical and Secondary Education, and it shows what is being done to provide continuous and systematic courses of training for promising students. It appears from this report that, taking County and County Borough Councils together, there are now 93 out of 110 such local authorities who provide scholarships in one form or another. The total number and value of the scholarships and exhibitions in force (*i.e.* those awarded and those continued and renewed from previous years) under the schemes of 90 of those 93 authorities during the year 1899–1900 were 19,971 and 156,793*l*. respectively. The scholarships are tenable at institutions of various ranks, and the number and value of those awarded annually in each class are as follows:—(1) At evening classes, 6766 (7862*l*.); (2) at technical and science and art schools, 3426 (17,064*l*.); (3) at secondary schools, 5593 (77,349*l*.); (4) at higher institutions and Universities, 679 (27,097*l*.); (5) at agricultural and horticultural schools, &c., 532 (9866*l*.); (6) at domestic science schools, &c., 1349 (12,199*l*.); (7) for elementary teachers, 1626 (5356*l*.). A comparison of these figures with similar returns obtained five years ago shows that a considerable increase has taken place in the number of scholarships tenable at permanent technical schools.

SCIENTIFIC SERIAL.

American Journal of Science, August.—Experiments on high electrical resistances, by O. N. Rood. The units of resistance employed were prepared by painting peroxide of manganese on strips of blue cobalt glass, then drying and immersing in a rosin wax bath at 150° C. It was found that the surface conduction of units prepared in this way in ordinary weather was practically zero. The aluminium leaf electrometer used in the measurements is also described. It was found possible to build up a set of high resistances with values from 32,000 to 14,000,000 megohms.—Mineralogical notes, by A. J. Moses. A description of mercuric iodide from New South Wales, some new forms on Bergen Hill pectolite and on atacamite crystals from Chili, realgar crystals from Snohomish County, Washington, vesuvianite from New Mexico, chrysoberyl from New York City, and a pyroxene crystal from the copper mines of Ducktown, Tenn.—On the motion of compressible fluids, by J. W. Davis.—The action of sodium thiosulphate on solutions of metallic salts at high temperatures and pressures, by J. T. Norton, jun. Solutions of various salts which are incompletely precipitated by sodium thiosulphate at the ordinary temperature were heated under pressure in sealed tubes at 120°–140° C. In many cases the reaction became complete, the whole of the metal being precipitated as sulphide or hydroxide. In a few cases the reaction was indeterminate.—Secondary undulations shown by recording tide gauges, by A. W. Duff.—Mathematical notes to rival theories of cosmogony, by O. Fisher.—Studies of Eocene Mammalia in the Marsh collection, Peabody Museum, by J. K. Wortman.—The electromagnetic effects of moving charged spheres, by E. P. Adams. The deflection of a magnetic needle caused by the rotation of two electrically charged spheres was measured, and in opposition to the views recently published by Cremieu, the deflections observed agreed with those calculated theoretically within the limits of experimental error.—The nadir of temperature and allied problems, by J. Dewar.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 20.—On the Behaviour of Oxy-hæmoglobin, Carbonic-oxide-hæmoglobin, Methæmoglobin and certain of their Derivatives, in the Magnetic Field, with a Preliminary Note on the Electrolysis of the Hæmoglobin Compounds, by Arthur Gamgee, M.D., F.R.S., Emeritus Professor of Physiology in the Owens College, Victoria University.

The following are the conclusions to which the author has been led by his experiments:—

(1) The blood-colouring matter, oxy-hæmoglobin, as well as carbonic-oxide hæmoglobin and methæmoglobin, are decidedly diamagnetic bodies.

(2) The iron-containing derivatives hæmatin and acethæmin are powerfully magnetic bodies. The differences in magnetic behaviour between the blood-colouring matter and acethæmin and hæmatin point to the profound transformation which occurs in the hæmoglobin molecule when it is decomposed in the presence of oxygen.

(3) The preliminary study of the electrolysis of oxy-hæmoglobin and CO-hæmoglobin renders it probable that, in the blood-colouring matter, the iron-containing group, on which its physiological properties depend, is (or is contained in) an electro-negative radical; according to analogy, the iron in such a compound would possess diamagnetic and not magnetic properties.

PARIS.

Academy of Sciences, August 12.—M. Fouqué in the chair.—A criterion for the recognition of singular points of the uniform branch of any monogenous function, by M. G. Mittag-Leffler.—On the infinitely small deformation of an elastic ellipsoid submitted to known forces on its boundaries, by MM. Eugène and François Cosserat.—Verification of the relation which exists between the characteristic angle of deformation of metals and the coefficient of restitution of their elasticity, by M. G. Gravaris.—On the colour of the ions, by M. G. Vaillant. The theory of ions applied to the coloration of solutions leads to the following consequences: in completely dissociated solutions containing only one coloured ion, the coloration is independent of the nature of the other ion; if the ionisation is incomplete, the coloration should vary with the concentration and nature of the non-coloured ion; and, finally, the coloration of a solution of any concentration ought to be related to its degree of dissociation by a formula with two moduli, and two only. All these conclusions were confirmed experimentally by a study of solutions of the permanganates of potassium, barium and zinc.—On the value of the molecular heats at the boiling point, by M. de Forcrand.—The action of benzoyl chloride upon trioxymethylene in presence of zinc chloride, by M. Marcel-Descudé.—A method for the prevention of hail, by

M. G. M. Stanoiéwitch. The use of a small captive balloon fitted with a deep-toned electrically-driven bell or siren is suggested as a means of breaking up hail clouds.

NEW SOUTH WALES.

Royal Society, June 5.—Mr. G. H. Knibbs in the chair.—On a new rock allied to nepheline phonolite, from Kosciusko, New South Wales, by F. B. Guthrie, Prof. David, F.R.S., and W. G. Woolnough. The Kosciusko rock is characterised by its large proportion of nepheline which dominates all the other minerals. The nepheline occurs in micro-porphyritic idiomorphic crystals. The soda-augite ægirine is also abundant, and there is a small amount of glassy material in the base through which are scattered delicate acicular crystals and microlites of felspar. A few small amygdules may be noticed, not sharply marked off from the surrounding rock; they consist of a shell formed chiefly of analcime enclosing secondary calcite. The specific gravity of the rock varies from 2·43–2·5. The rock differs conspicuously from typical phonolites in the following respects:—(1) low silica percentage; (2) entire absence of phenocrysts of sanidine. It is a felspathoid rock, and although its silica percentage allies it with the basalts, its mineral constitution, chemical composition and low specific gravity link it with the phonolites. So far as the authors are aware, it is unlike any rock that has hitherto been described from any part of the world.—Preliminary notes on the intermediary host of *Filaria immitis*, Leidy, by Mr. Thos. L. Bancroft. *Filaria immitis*, a worm-parasite of the dog, common throughout the world, but more especially in the warmer parts, of from five to ten inches in length, the males being the smaller, is found generally in the right ventricle of the heart and in the pulmonary artery. The so-called embryos, 1/90 in. × 1/3500 in., are produced in great numbers; the late Dr. Spencer Cobbold taught that an intermediary host was necessary to transmit the parasite from one dog to another. Among others, Grassi, Sonsino and J. Bancroft endeavoured to discover this intermediary host. The dog-flea (*Pulex serraticeps*), the various dog lice, and ticks were examined, but with negative results. The author for thirteen years past had endeavoured to find the intermediary host, examining *Pulex serraticeps;* the common horse-fly, *Stomoxys sp.?; Culex vigilax*, Skuse—a day-flying mosquito; the intestinal worm parasite of the dog—the *Anchylostoma* or *Dochmius trigonocephalus.* The possibility of metamorphosis being essential seemed doubtful, the embryo might, it was thought, go through a cold stage for several days in the body of an insect and then develop, after introduction into the body of the dog. A puppy, who ate 110 *Stomoxys* flies gorged with filariated blood, in one month showed after a series of experiments, extending over nearly a year, that such an hypothesis was untenable; and moreover, that the time taken by the young filaria to arrive at sexual maturity was not less than seven months nor more than twelve. After discussing Grassi's discovery of the intermediary host of *Filaria immitis*, viz. the *Anopheles maculipennis*, Meigen, syn. *A. claviger*, Fab., and the statements of a paper by Grassi and Noè on "the propagation of the filariæ of the blood exclusively by means of the puncture of peculiar mosquitoes," the author states we are now able to give an exact account of the life-history of both *Filaria nocturna* and *F. immitis.* The sexually mature worms in man or dog produce embryos, which swim in the blood: the mosquito on biting abstracts some of the embryos, these develop in the mosquito's body, and in about three weeks are capable of entering their final or definite hosts, passing into the puncture made by the mosquito in the skin; they then advance to sexual maturity in the course of about a year. The position in the mosquito's body during the metamorphosis of the embryos distinguishes *F. nocturna* from *F. immitis*, the former being in the thoracic muscles, the latter in the malpighian tubes, at their maximum development; the latter are distinguished as being shorter and thicker. It has been learnt that mosquitoes live for long periods, and not merely a few days as was formerly supposed, and that during their life they bite frequently. In Europe, *Anopheles maculipennis* plays the *rôle* of host for the malarial parasite, for *F. immitis* and it is believed also for *F. nocturna;* in Australia the house-mosquito, *Culex skusii*, Giles, is host for both *F. nocturna* and *F. immitis*, and probably also for the malarial parasite.

Linnean Society, June 26.—Mr. J. H. Maiden, president, in the chair.—On the occurrence of diatoms and radiolaria in the Rolling Downs Formation (Lower Cretaceous) of Queensland, by Prof. David, F.R.S., W. S. Dun and W. H. Rands.—Notes on an aboriginal grave in the Darling River District, N.S.W., by Graham Officer. Certain objects of aboriginal manufacture found over a large area of the western division of New South Wales have hitherto been somewhat of a puzzle to anthropologists, and precise information about them is very difficult to obtain. The objects in question are of two types, one of which has already received consideration from Mr. W. R. Harper in the Society's *Proceedings* for 1898 (p. 420). A second type is described in the present paper, some examples of which were found on an aboriginal grave arranged in a circle about three feet in diameter. The author concludes that the objects of both types had a phallic significance; also that those of the first type were used to mark the graves of men, while those of the second type were placed on the graves of women, possibly also of youths who had not attained their tribal majority.—The "shot-hole" fungi of stone-fruit trees in Australia, by D. McAlpine. The shot-hole effects produced in stone-fruit trees are shown to be due to an effort on the part of the tree to get rid of a parasite or other irritating agent, and the formation of a callus bounding the spot is a special property of the living tissue. At least twenty fungi are known at present to be the cause of "shot-hole," and of these one-half are found in Australia.—Australian Psyllidæ, part ii., by W. W. Froggatt. Twenty-four species referable to three subfamilies are described as new.—On the "onvar" of Malekula, New Hebrides, by Walter R. Harper. The "onvar" or thumb-guard of the Malekulan archer was first mentioned by Captain Cook, and a decorated form of it—probably part of the insignia of a chief—was described by Forster. The more common form is a circular piece of hard though light wood about 3 cm. in thickness, 12 cm. outside diameter at the base, bevelled off to an outside diameter of 7 cm. at the top and pierced by a hole large enough to admit the hand of the wearer, the average diameter of the opening in five specimens being 6·5 cm.

THE HISTORY OF PHYSIOLOGY.

Lectures on the History of Physiology during the Sixteenth, Seventeenth and Eighteenth Centuries. By Sir M. Foster, K.C.B., M.P., M.D., D.C.L., Sec. R.S., Professor of Physiology in the University of Cambridge. Pp. 310. (Cambridge: University Press.)

THERE is no more fascinating chapter in the history of science than that which deals which physiology, but a concise and at the same time compendious account of the early history of the subject has never before been presented to the English reader. Physiologists therefore owe a debt of gratitude to Sir Michael Foster for supplying a want which was widely felt. The following is a short account of the contents of the book, to which no higher praise can be given than to say that it is worthy of the reputation of its author.

As already remarked, the subject itself is a fascinating one, and it is rendered the more so by the manner in which it is treated in these lectures,[1] which abound with interesting biographical details and with quotations from the works of the early masters of science. The work is one which will interest circles far wider than physiological, for so intimately are the natural sciences interconnected that it is impossible to write the history of any one without constantly referring to points in the history of others. This must especially be so with physiology, which is directly based upon anatomy, physics and chemistry. It is not therefore surprising to find that the first lecture is devoted to the work of Vesalius and the early history of anatomy.

Andreas Vesalius was born in Brussels on December 31, 1514; his father was apothecary to the Emperor Charles V., and his mother, "to judge by her maiden name, Isabella Crabbe, was probably of English extraction." He studied at Louvain and at Paris, in the latter place under Jacobus Sylvius and Guinterius. That was a time when neither anatomy nor medicine was recognised outside the pages of Galen: if the facts were not reconcilable with Galen, so much the worse for the facts; it was rank heresy to teach otherwise. But Vesalius early determined to investigate for himself, and, although he had to resort for his material to the graveyard and even to the gibbet, where, he says, "'to the great convenience of the studious, the bodies of those condemned to death were exposed to public view,'" he was not to be deterred from his purpose. At the age of twenty-one he migrated to Venice, and was almost immediately appointed to teach surgery and anatomy at the University of Padua. Here his opportunities for study were far greater than in Paris or Louvain, and after five years' patient labour he produced his great work "On the Structure of the Human Body," which was published at Basel in 1543. "This book," says Foster, "is the beginning, not only of modern anatomy, but of modern physiology."

It is true that Vesalius dealt but little with physiology, being for the most part content to teach the Galenic doctrines, he himself saying that "'he accommodated his statements to the dogmas of Galen, not because he thought that these were in all cases consonant with truth, but because in such a new great work he hesitated to lay down his own opinions, and did not dare to swerve a nail's breadth from the doctrines of the Prince of Medicine.'"

But he no doubt recognised that the new truths about anatomy which he was promulgating involved the modification or rejection of the old dogmas. And it is certain that the publication of his work was so received, for the storm of opposition which it raised from the orthodox teachers of the time proved sufficient to terminate Vesalius' career as an anatomist. In disgust he burnt all his manuscripts, and accepted the post of Court Physician to Charles V. This was in 1544, and, although he lived some twenty years longer and was able to see his work beginning to bear fruit, he himself produced no more.

While it is clear that Vesalius did not really believe that the blood passed from the right heart to the left through the septum, as Galen supposed, it was Servetus, the Unitarian physician who was burnt at the stake by Calvin, who, in a theological work written in 1546 and published in 1553, first clearly enunciated the opinion that the communication occurs through the lungs. But how far this opinion was the result of experiment and observation and how far it was mere conjecture is difficult to say; in any case Servetus' suggestion had little influence upon the progress of physiology, nor was it accepted until, in the course of the following century, the proofs were furnished by Harvey. Like all great discoveries, that of Harvey was led up to by the work of previous observers, more than one of whom arrived very near the truth. This is the case, as we have seen, with Servetus so far as the pulmonary circulation is concerned, with Cæsalpinus, and with Realdus Columbus (who is, however, supposed to have "cribbed" from a manuscript of Servetus). Fabricius of Aquapendente, Harvey's master, supplied in his discovery of the valves of the veins one of the most important facts upon which Harvey's doctrine of the circulation was based. But there can be no difference of opinion as to the fact that the history of physiology itself and all advance in surgery and medicine begins with Harvey, for until the action of the heart and the circulation of the blood were understood there could be no correct understanding of the working of any part of the animal mechanism. To this subject the second lecture is accordingly devoted.

Harvey was born in 1578 at Folkestone. He took his degree at Cambridge in 1597, studied four years under Fabricius at Padua, became physician to St. Bartholomew's Hospital in 1609, and "ventured in 1615 to develope, in his 'Lectures on Anatomy' at the College of Physicians, the view which he was forming concerning the movements of the heart and of the blood. But his book, his *Exercitatio*, did not see the light until 1628." He was physician to Charles I., after whose death "he retired into private life, publishing in 1651 his treatise, *De generatione animalium*, . . . and on June 3, 1667, he ended a life remarkable for its effects rather than for its events."

"His wonderful book, or rather tract, for it is little more, is one sustained and condensed argument." Up

[1] The lectures were delivered as the "Lane Lectures" at the Cooper Medical College in San Francisco in the autumn of 1900.

to the time of Harvey it was supposed, and was commonly taught, that the heart acted like a suction pump, not like a force pump; that the diastole was the active, the systole the passive, condition; that the blood ebbed and flowed in the veins and arteries; that air and vital spirits passed to the heart by the pulmonary arteries; that the blood, or part of the blood, passed from the right ventricle to the left through pores in the septum. Harvey's results were arrived at partly by anatomical observation and inference, but chiefly by physiological observation and experiment. His arguments were founded,

"not on general principles and analogies, but on the results of 'frequent appeals to vivisection.' 'When first I gave my mind to vivisection, as a means of discovering the motions and uses of the heart, and sought to discover these from actual inspection, and not from the writings of others, I found the task so truly arduous, that I was almost tempted to think, with Frascatorius' (a Veronese doctor of the sixteenth century and more a poet than a man of science), 'that the movement of the heart was only to be comprehended by God. For I could neither rightly perceive at first when the systole and when the diastole took place, nor when and where dilatation and contraction occurred, by reason of the rapidity of the movement, which in many animals is accomplished in the twinkling of an eye, coming and going like a flash of lightning.' But the patient and prolonged study of the heart in many animals showed him that 'the motion of the heart consists in a certain universal tension, both of contraction in the line of its fibres and constriction in every sense, that when the heart contracts it is emptied, that the motion which is in general regarded as the diastole of the heart is in truth its systole,' that the active phase of the heart is not that which sucks blood in but that which drives blood out."

In this way Harvey came to see clearly, what had been already dimly guessed at by more than one of his forerunners, that the right heart receives blood from the venæ cavæ and pumps it through the lungs into the left heart. From it there followed

"another conception, which, however, 'was so new, was of so novel and unheard of a character, that in putting it forward he not only feared injury to himself from the enmity of a few, but trembled lest he might have mankind at large for his enemies.' . . . To this new view he was guided by distinctly quantitative considerations. . . . This is what he says: 'I frequently and seriously bethought me, and long revolved in my mind, what might be the quantity of blood which was transmitted, in how short a time its passage might be effected, and the like; and not finding it possible that this could be supplied by the juices of the ingested aliment without the veins on the one hand being drained, and the arteries on the other hand becoming ruptured through the excessive charge of blood, unless the blood should somehow find its way from the arteries into the veins, and so return to the right side of the heart; I began to think whether there might not be *a motion, as it were, in a circle*. Now this I afterwards found to be true. . . .' To that true view of the motion of blood he was led by a series of steps, each in turn based on observations made on the heart as seen in the living animal."

His argument is essentially a physical mechanical argument, and his demonstration was the "deathblow to the doctrine of the distribution of 'animal spirits' by the blood," although he does not himself deal with that doctrine and only refers to it incidentally.

The revival of the study of physics under Galileo and his pupils in the seventeenth century had a marked influence upon the progress of the new physiology, and forms the subject-matter of the third lecture. In particular Borelli (1608–1679), the famous professor of mathematics at Pisa, influenced largely by his friendship with Malpighi, set to work to apply physical laws to physiological problems. His great work, "De motu animalium," was not published until just after his death, but what is printed in it had been taught publicly long before, and much of the work had long been in manuscript.

A large part of Borelli's work is devoted to the special mechanical problems. He treats in succession of muscular mechanics, of standing, walking, running and locomotion in general, and investigates them by the aid of mathematics (his discussions concerning these problems may still be read with profit); he even attempts to solve the nature of muscular motion by mechanical methods. He estimates the force of muscles and of the heart, shows how the elasticity of the arteries aids the flow of blood through them, deals with the mechanics of respiration, and anticipates the modern attempts to account for all the phenomena of secretion by a mechanical explanation. Even nervous phenomena are explained by him as due to oscillations transmitted by a fluid, and in the same spirit he discusses "the generation and nutrition of both plants and animals, and even the nature of several diseases. . . . He was so successful in his mechanical solutions of physiological problems that many coming after him readily rushed to the conclusion that all such problems could be solved by the same methods."

The work of Marcello Malpighi (1628–1694), the friend of Borelli, and his colleague at Pisa during three years, although the greater part of his life was spent at Bologna (his native city), is dealt with at great length in the fourth lecture of the series. With his character the lecturer has obviously the fullest sympathy.

"Kindly even to softness, ready to give his affections to those who seemed drawn to him, devoted wholly to those who had won his love, modest and retiring even to timidity, bold only in the interests of truth and right, never in his own . . . beloved for the sake of himself, even by those who were not competent judges of his talents and his works."

Four years of his life, viz. from 1662–1666, Malpighi spent at Messina, as professor of medicine, and it was here that he began those researches into the minute anatomy of fishes and invertebrates which "opened up in his mind views as to the real nature of the like but more complex structures of man and the higher animals."

Malpighi's relations to the young Royal Society of London are well known. These relations began in 1667 and continued throughout his life, and the Society "had the honour of publishing and of bearing the expense of publication of the greater part of Malpighi's works." His work was essentially founded upon the use of the microscope, which had but recently been invented, or rather improved and rendered an instrument available for research. He and Nehemiah Grew, independently and almost simultaneously, laid the foundations of our knowledge of the structure of plants. He may also be regarded as the founder of embryology, for he gave the first adequate description of the changes undergone by the developing chick *in ovo*. He described the capillary circulation, and thus completed the immortal discovery of Harvey, and although not the first to observe the corpuscles of the blood, for he was anticipated in this by a few years by Swammerdam, his observation was independent of Swammerdam's, and made long prior to its publication. The extent of his researches into the structure of the tissues and organs is testified to by the number of parts to which his name is attached, *e.g.* the Malpighian tubules of insects, the rete Malpighii of the epidermis, the Malpighian bodies of the spleen and kidney. "Whatever part of natural knowledge he touched he left his mark; he found paths crooked and he left them straight; he found darkness and he left light."

The effect upon physiology of the new knowledge of chemistry which was dawning in the seventeenth century, as the result, in large measure, of the work of van Helmont (1577–1644), mystic though he was in many matters, and of his immediate successors, is dealt with in the fifth and sixth lectures. Practising as a physician, van Helmont was nevertheless mainly occupied, at Vilvorde in Belgium, with carrying out chemical observations and experiments. Although he received the Elijah cloak of Paracelsus, whose spiritualistic doctrines he adopts and even develops, and although he was still imbued with the Galenic doctrines, in spite of the fact that Harvey's work was already published when he wrote and must have been known to him, he nevertheless shows himself to be

"a patient, careful, exact observer . . . who watches, measures and weighs, who takes advantage of the aid of instruments of exact research, who reaches a conclusion by means of accurate quantitative estimations. . . . Throughout the whole of his writings is seen the continued endeavour to weave his exact chemical physical knowledge and his spiritualistic views into a consistent whole. . . . These two sides of van Helmont's character are not unfitly indicated by the two words *gas* and *blas*, 'two new terms,' he himself says, 'introduced by me because a knowledge of them (*i.e.* of the things they indicate) was hidden from the ancients.' By '*blas*' he meant an invisible spiritual agency which directs and governs material changes: this is the *archeus* of Paracelsus. By '*gas*' he clearly meant what we now call carbonic acid gas. . . . He gives it that name because the sound is not so far from that of 'chaos,' the unformed womb of all things."

He shows that gas is produced by the combustion of charcoal, by the fermentation of fruits, by the ignition of gunpowder. He gives an account of digestion, which he likens to fermentation. He recognises the essentially acid nature of the gastric secretion and its chemical action upon food. He describes absorption from the intestines as being due, in part at least, to diffusion. But he does not grasp the idea of the use of air in breathing; he still clings to the old notion of "vital spirits." He anticipates modern physiology in teaching that the tissues prepare their own substance independently from the blood. But, to judge by his writings, van Helmont was at heart more pleased with his blas than with his gas. "He allows to man alone a sensitive soul. The throne of this soul is in the pylorus; 'there it sits and there it abides all life long.' He gives reasons for this conclusion, *e.g.* a great emotion is felt at the pit of the stomach; a severe blow in the pit of the stomach will stop the heart."

Van Helmont was followed by Franciscus Sylvius (1614–1672) in explaining many of the phenomena of the body by the help of chemical science, and by Regner de Graaf (1641–1673) in his observations upon digestion. De Graaf was the first to obtain pancreatic juice, saliva, and bile from artificial fistulæ; his methods are used at the present day. And soon afterwards the knowledge of glands and their functions was still further advanced by the discoveries of Peyer (1653–1712), and von Brunner (1653–1727), of the glands in the intestine now known by their names.

But the progress of chemical science was destined to be arrested for many years by the speculations and teaching of George Ernest Stahl (1660–1734), who was successively court physician at Weimar, professor of medicine at Halle, and physician to the King of Prussia. "He was an accomplished chemist, and his name must always be borne in mind in dealing with the history of science, if for nothing else, for the reason that he was the author of the famous theory of phlogiston, which ruled with a rod of iron, as it were, the thoughts of natural philosophers for a hundred years."

Stahl maintained the view that the chemical changes of the living body were entirely different from those of the laboratory, that they were directly governed by the sensitive soul, which pervaded all parts, which not only set the chemical agent in motion, but was itself the agent. "He thus stands forth at the close of the seventeenth century as the founder of 'animism,'" a doctrine which, under the name of a vital principle, maintained itself through the succeeding centuries, and exists in a modified form even at the present day.

The seventh lecture of the series, which is devoted to the English school of the seventeenth century and deals mainly with the evolution of the physiology of respiration, is one of great interest, bound up as it is with the early history of the Royal Society. The fundamental experiment that a candle goes out, an animal dies, in a space deprived of air is due to Robert Boyle (1660). Robert Hook in 1667 showed the Fellows of the Royal Society that an animal can be kept alive by artificial respiration without any movement of the lung or chest wall; that the air alone, coming in contact with the blood, is the essential part of respiration. Richard Lower (1631–1690), besides his well-known work on transfusion and on the structure and action of the heart, also carried the subject of the physiology of respiration still further by showing that the change of the blood from venous to arterial is merely a change of colour due to air; he concluded that this entrance of fresh air into the blood is as necessary for the body as for the combustion of fuel. But it was left for John Mayow (1643–1679) to prove that it is a part only of the air to which this property is due, and to this part he gave the name of "nitro-aereal or igneo-aereal" spirit, which was neither more nor less than that which we now term oxygen. This was before Stahl had introduced the phlogiston theory, the essence of which was that when a combustible body was burned, phlogiston departed from it: it lost weight. Mayow is quite explicit on this point, showing that when antimonium is burned it increases considerably in weight. "'Now we can hardly conceive that the increase of weight of the antimonium arises from anything else than from the igneo-aereal particles inserted into it during the calcination.'"

Mayow fully identified burning and breathing. He found that either a lighted candle or an animal in an enclosed space exhausts a certain proportion of the air. "'We may infer,'" he says, "'that animals and fire deprive the air of particles of the same kind.'" "'It is clear,'" he adds elsewhere, "'that even the very plants seem to have some need of breathing, some need of drawing air into themselves.'" "In his tract, 'On Respiration,' he gives an exposition of the mechanics of breathing which might almost find its place in a text-book of the present day." He further supposed that the heat of the body is kept up by union of tiny nitro-aereal particles with salino-sulphureous (*i.e.* combustible) particles of the blood—a "sound theory," says Foster, "of animal heat," although now superseded, as will be subsequently seen, by one which places the union in the tissues themselves.

But the "great truth" which had been reached by the labours of these English physicists and physiologists died out with Mayow.

"The world had to wait for more than a hundred years till Mayow's thought arose again, as it were, from the grave in a new dress, and with a new name; and that which in the first years of the latter half of the seventeenth century as igneo-aereal particles shone out in a flash and then died away again in darkness, in the last years of the eighteenth century, as oxygen, lit a light which has burned, and which has lighted the world with increasing steadiness up to the present day."

The rise of the modern doctrines of combustion and respiration, the work of Black, Priestley and Lavoisier, is dealt with in the ninth lecture of the series, the eighth being devoted to the researches of Réaumur, Spallanzani, Stevens and John Hunter on gastric digestion. Although van Helmont had shown the stomach to be a great digestive organ and the acid character of its secretion its essential feature, subsequent authorities had ignored or denied its agency in digestion. It was regarded as having mainly a mechanical function. But Réaumur, who was eminent in other sciences besides physiology, showed clearly, by causing a kite to swallow small metal tubes closed at each end by a grating and filled with food, that without any trituration and with no semblance of putrefaction both meat and bone became dissolved whereas vegetable grains were little altered. He even obtained gastric juice from pieces of sponge included in the tubes, and found it to be acid. Spallanzani, who was born in 1729 and the centenary of whose death was celebrated two years ago, was successively professor of logic at Reggio and of natural history at Modena and at Pavia. He wrote on many subjects of natural history, but in physiology chiefly upon respiration and digestion—experimenting by Réaumur's methods upon all kinds of animals and even upon himself. He obtained gastric juice as Réaumur had done, but was successful in showing its activity *in vitro*, in which Réaumur had not succeeded; he failed, however, to detect its acid character. Similar experiments to those of Spallanzani were made independently by Stevens, of Edinburgh, who announced his results in an inaugural thesis in 1777, the same year as the publication of Spallanzani's first paper on the subject. Stevens also obtained "pure gastric fluid" from the stomach of a dog killed during fasting, and found that at the body temperature it readily dissolved meat, and he made besides numerous experiments by Réaumur's method on digestion *in vivo*. John Hunter, in 1772, "constantly found that there was an acid, though not a strong one," in the gastric juice, but later on he is led to regard this as not essential. The acidity which van Helmont had insisted upon at the beginning of the seventeenth century was not accepted until the nineteenth.

Stephen Hales (1677–1761) was a Fellow of Corpus Christi College, Cambridge, and became perpetual curate of Teddington in Middlesex. "He was devoted to science; he had begun to experiment while at Cambridge in the 'elaboratory' of Trinity College," where Bentley was then master; "and he continued his researches amid his parish duties at Teddington." He was the first to determine by experiment upon the living animal (horse) the pressure of the blood in the arteries, and he dealt also with the flow of sap in plants. "His writings contain the first clear enunciation of the existence of gases in a free and in a combined condition."

It is the merit of Joseph Black (1728–1799), who was professor of chemistry successively in Glasgow and Edinburgh, to have rediscovered the "gas" of van Helmont: to this he gave the name of "fixed air." He proved that it is given off in combustion, in fermentation and in respiration; that it is irrespirable; and he at first thought that it formed the irrespirable portion of the atmosphere. But Rutherford, of Edinburgh, in his inaugural thesis in 1772, showed that after the "fixed air" (caused by combustion) had been removed by caustic alkali, "a very large proportion of air remains which extinguishes life and flame in an instant." This was nothing else than the discovery of *nitrogen*, although its connection with nitre was first shown later by Cavendish.

Just as Black rediscovered the *gas sylvestre* of van Helmont, so Priestley (1733–1804) and Lavoisier (1743–1794) rediscovered the gas which Mayow had termed the igneo-aereal spirit and which was ultimately named by Lavoisier *oxygen*. Priestley was a Unitarian minister—"a man of letters as well as man of science, prolific theologian and ardent politician." He was the first to discover that the something in the air which is removed by the burning of a candle or by the respiration of an animal is restored by vegetation. He obtained from mercuric oxide (*mercurius calcinatus per se*), by heating it with a burning glass, a quantity of "air." "'Having got about three or four times as much as the bulk of my materials, I admitted water to it, and found that it was not imbibed by it. But what surprised me more than I can well express was that a candle burned in this air with a remarkably vigorous flame . . . and a piece of red-hot wood sparkled in it.'"

"He obtained the same gas from red precipitate and from minium; he found that a mouse lived well in it . . . that it was four or five times as good as common air."

Imbued with the phlogistic theory, he regarded it as common air which was freed from phlogiston, "dephlogisticated air," and he endeavoured to explain all his own results as well as the changes occurring in combustion and respiration on the same theory. Thus although in 1774 he prepared oxygen he did not discover it in the true sense of the word, because he failed to understand his discovery. This was reserved for Lavoisier, who, in the year following (1775), published his paper "On the nature of the principle which combines with metals during their calcination," in which he conclusively showed that the principle is taken up from the air, is part of the air. Two years later he demonstrated that the same substance "is the constructive principle of acidity," and he called it the acidifying (or oxygine) principle.

The composition of the atmosphere now became clear; the discovery, or rediscovery, of nitrogen (or *azote*, from its inability to support life) naturally followed, and the gaseous exchanges in the lungs between oxygen from the air and Black's "fixed air," or "aeriform calcic acid," as it was at first termed by Lavoisier, were demonstrated, as we at present understand them. "Thus at a single stroke did this clear-sighted inquirer solve the problem of oxidation, and almost, if not quite, the problem of respiration." This was in 1777.

Three years later Lavoisier and Laplace published their celebrated memoir on heat. In this they definitely state—as the result of measurements of the amount of heat produced by the combustion of a given weight of carbon when burned to carbonic acid, and the amount given out by an animal with the production of a given quantity of carbonic acid—that "respiration is a combustion, slow it is true, but otherwise perfectly similar to the combustion of charcoal. It takes place in the interior of the lung . . . The heat developed by this combustion is communicated to the blood . . . and is distributed over the whole animal system." Later Lavoisier recognised that the combustion of hydrogen, which had been discovered by Cavendish in 1781, takes a part in the production of animal heat. Not until long after Lavoisier—not, in fact, until well into the nineteenth century—was it recognised that the combination of oxygen with carbon and hydrogen occurs, not in the lungs, but in the tissues. Lavoisier was but fifty years old when he was swept away, in 1794, in the maelstrom of the Revolution; all too soon for the science which he had done so much, and in so short a time, to advance.

The tenth and final lecture is devoted to the older doctrines of the nervous system. The views of Vesalius and of Descartes (1596–1650), of Willis (1621–1675) and Glisson (1597–1677), of Borelli, of Stensen (1638–1686) and of Haller (1708–1777) are here set forth, and the history of the doctrine of "irritability" of tissues, first enunciated by Glisson and afterwards by Haller, is described. But, as a matter of fact, the physiology of the nervous system is almost entirely the product of the nineteenth century; before that it can scarcely be said to have a history; everything was obscure, and the place of facts was occupied for the most part by vague speculations.

One of the most prolific subjects of such speculation was the seat of the soul, which was assigned by van Helmont (as we have already seen) to the pit of the stomach, by Descartes to the pineal gland, by Haller, with better reason, to the medulla oblongata. "But we have learned much since Haller's time." . . . "And if he," adds Foster, "with the knowledge and the means at his command, seems to us to-day to have often gone astray, shall not we ourselves one hundred years hence still more often appear to have gone astray?" To which it may perhaps be replied that, although it will always be human to err, yet the means at our command are so much more complete and the methods so much more accurate that it is far less likely that we shall take a start in a wrong direction, or, having taken it, shall continue in it; in this at least we have an advantage over our eighteenth century predecessors, whose methods were, comparatively speaking, rough and their means and opportunities relatively limited.

Whilst endeavouring in the above account to give a general idea of the character of the book with which Sir Michael Foster has enriched the world of science, it is by no means an easy task to do adequate justice to the mine of literary and historic research which the author has laid open to view. But if a perusal of this account serves to induce others to go to the original, we can promise them that they will find it as interesting a story as may be met with for many a long day. And it is to be hoped that the perusal of Sir Michael Foster's history will stimulate the desire of its readers to make the direct acquaintance of the great authors who, during the three centuries under review, laid the foundations of modern physiology and, with it, of the sciences upon which modern physiology is based.

E. A. S.

FILTRATION OF WATER.

Water Filtration Works. By James H. Fuertes. Pp. xviii + 283. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1901.) Price 10*s*. 6*d*.

FILTRATION, which is generally regarded as an essential process in the provision of domestic water-supplies for large towns in England, especially when rivers constitute the source of supply, has been neglected to a considerable extent in the United States, and, therefore, the publication of a book, by an American engineer, dealing wholly with this subject, will be particularly valuable if it should lead municipalities in the United States to the more general adoption of this safeguard against the distribution of water to large populations in a condition dangerous to health. Polluted river waters, in their natural condition, have proved very fatal to our troops in South Africa, as shown by the high rate of mortality from enteric or typhoid fever; and the author, at the commencement of his book, draws a very striking contrast between the annual death-rate from typhoid fever per 100,000 persons in cities supplied with pure or filtered water, such as the Hague, Munich, Dresden, and Berlin, with a typhoid death-rate of only from 4·7 to 7, and Washington, Louisville, and Pittsburg, supplied with unfiltered river water, where the yearly typhoid death-rate for several years has averaged 71, 74, and 84, respectively, per hundred thousand of population. River waters are to some extent purified by natural agencies during their downward flow if no fresh causes of contamination are introduced, depending on the extent of their original pollution and the length of their uncontaminated flow; and the impurities in suspension may to a considerable extent be removed by causing the water to remain at rest in a settling basin for a certain period before distribution, so that the larger, heavier particles are deposited at the bottom of the basin. Generally, however, after this subsidence has taken place, the finer, lighter particles and micro-organisms remain in suspension in the water, as well as substances in solution; and the final purification can only be effected by filtration, assisted often by aëration, and sometimes by chemical processes.

After an introductory chapter and a chapter on intakes, sedimentation, and settling basins, the author proceeds to the consideration of his main subject, filtration. Two methods of filtration are described for the purification of water-supplies, namely slow sand-filtration, denoted as the English method, from its first introduction and general use in this country, and rapid sand-filtration, requiring the preliminary addition of a chemical solution, termed a coagulant, to render this rapid system efficient, which, being a distinctly American invention, is called the American method. Two chapters are devoted to the consideration of each of these methods in succession, the first in each case discussing the theory, efficiency, and influences of different arrangements and modifications of slow, and of rapid sand-filtration respectively, and the second chapter dealing with the design, construction, and working of slow, and of rapid sand-filters. Following these four principal chapters of the book, is a chapter giving a summary of the relative merits of the two methods of filtration; instances in which a combination of the two methods might be advantageous; and brief descriptions of the Anderson, Pasteur-Chamberland, Worms, and Maignen filtering processes. The book concludes with a chapter on the location, design, and construction of filtered-water reservoirs.

The slow sand-filtration method for the purification of water is well known, and its efficiency has been fully established by long experience in England; and it appears to be the only method, aided by aëration, by which very turbid and polluted river waters, such, for instance, as the waters of the tidal River Húgli, which have to furnish the supplies for Calcutta and Howrah, can be sufficiently purified to serve for a domestic supply. Rapid sand-filtration is a comparatively novel method of purification; and the sand filters for this process consist usually of a layer of coarse grains of quartz sand, 2½ to 3 feet thick, placed in a tank of steel, iron, or wood, from the bottom of which the filtered water is led, through strainers to prevent the escape of the sand, into pipes for conveying away the supply for distribution. Aluminium sulphate has hitherto proved the most suitable coagulant, in which the sulphuric acid enters into combination with the calcium or magnesium carbonate in the water, setting free the aluminium hydrate which forms flocculent masses with the fine suspended matter in the water, and, adhering to the grains of sand as the water passes through the filter, covers them and the bed generally with a gelatinous film, which arrests the bacteria as well as the finest particles in the water, and ensures the efficiency of the filter. When the filter becomes clogged by these impurities, as indicated by a reduction in the flow through it, the bed of sand has to be stirred up and pure water forced up through it to remove the sediment. A rapid flow is less liable to be interrupted by frost; but the proportion of coagulant required in a rapid filter changes with the varying composition of the river water, and necessitates the constant supervision of an experienced chemist to regulate the dose to the conditions, for too small a quantity would reduce the efficiency of the purification, and too large a dose would impregnate the filtered water with alum, and, during the period of low alkalinity in the flood stage of the river, would leave free sulphuric acid in the water, which would be injurious to the pipes.

INTELLIGENCE AS THE SOUL OF THE UNIVERSE.

Modern Natural Theology; With the Testimony of Christian Evidences. By Frederick James Gant, F.R.C.S., &c. Pp. xii+151. (London: Elliot Stock, 1901.) Price 2*s*. 6*d*. net.

IT is no doubt true that the older form of the "argument from design" is more or less discredited by the doctrine of evolution. Nevertheless, the author of the book before us is justified in holding that the argument itself is not disposed of, and that in a setting more strictly accordant with our present knowledge than that which Paley gave it, it is still a powerful weapon in the hands of the natural theologian. More, indeed, is gained under the conception of organic growth than is lost by the sacrifice of the older teleology; for Paley's statement of the case savours of deism, whereas under the more recent view there are distinct indications in the universe of a purpose which may be called moral. In so far as such a purpose is discoverable in nature, to that extent does deism retire into the background. This is the aspect of the matter which is put forcibly, if not very intelligibly, in the work before us. The difficulties inherent in the materialistic as well as the deistic position are, on the whole, well stated, and the way is shown to be open for the recognition of intelligence as the "mind or soul of the universe." Though the author guards himself in words which are capable of an orthodox interpretation, it may be questioned whether the argument from nature, in his way of presenting it, necessarily excludes pantheism. Mr. Gant would probably appeal to the second part of his book—which, dealing as it does more particularly with historical evidences, is somewhat outside our province—as supplying the needful corrective. On the whole, however, it must be allowed that, though his personal convictions are not in doubt, his reading of natural phenomena is more successful as a criticism of the deistic position than as an attack on pantheistic interpretations.

The book would have been better adapted for its purpose if its author had developed his argument in simpler language and with stricter attention to the ordinary rules of composition. Instances of confused diction are numerous; for example:—

"In all sentient living beings, mind is much moved by suffering for the maintenance, and thence the prolongation of life" (p. 54).

"Thus living beings tell their own story of identification with living species, or declare their bygone existence as extinct species" (p. 62).

Here Mr. Gant's meaning can only be guessed at. In other cases, though the sense may be easy to grasp, the language shows an almost Thucydidean disregard of grammatical construction. The following passage may serve as an instance :—

"This law of orderly sequence . . . is unlimited in the extent of its operation ; and having produced the face of Nature she now presents, so, doubtless, will the portrait change in the future" (p. 68).

Here is a not unfair specimen of the author's way of overloading his sentences :—

"The moveable coccyx terminates in a blunt point, which . . . is a rudimentary *tail*; with which so many animals are provided, with diverse uses, in climbing, *e.g.*, some apes ; as an additional leg in bounding, or a formidable weapon for striking, *e.g.*, the kangaroo" (p. 40).

This calls for criticism in more respects than one.

We pass over Mr. Gant's views on the subject of heredity. They are open to question, but the main point at issue is immaterial with regard to the purpose of the book. The like may be said of a curious misuse of the term "natural selection" on p. 42. The reference to spiders and scorpions as "insects" is less excusable.

It is fair to state that the abrupt and disjointed style—to use no harsher terms—into which the author so frequently falls does not appear to reflect a corresponding incoherence of thought. Within certain limits, his chapters give the impression that what he has to say, if he could only express it fitly, would be worthy of attention. It is unfortunate that he has failed to find a more attractive method of imparting conclusions many of which are in themselves sufficiently sound and sensible.

OUR BOOK SHELF.

The Distribution of Rainfall over the Land. By Andrew J. Herbertson, Ph.D., F.R.S.E. With 13 maps and a plate. (London: John Murray, 1901.)

EVERY meteorologist will be most glad to possess this very valuable work on the distribution of rainfall over the earth's surface. Dr. Herbertson seems to have spared no pains to utilise all the available material, and the result is that he is able to present us with rainfall maps for every month in the year, giving not only the seasonal distribution of rain, but a knowledge of the actual amount. Each map is accompanied by general remarks as to the position of the pressure belts, wind systems, and other useful information which are fundamental in studying the weather from month to month. Further, a map, with descriptions, &c., is given, illustrating the mean annual rainfall over the land surface. The book includes also a very useful set of curves showing the monthly distribution of rainfall in percentages of the annual fall for seventy-four selected stations. From these it can be seen at a glance whether a station receives the majority of its rainfall at one period of the year, such as Bombay, Pekin, Bathurst, &c., or whether there are two periods of rainfall each year, as at Colombo, Lagos, Peshawar, &c. The importance of keeping separate the rainfall that is received at one place during a year at the two monsoons and not combining them when there happen to be two periods of rainfall is of fundamental importance at the present day, and the volume before us will help to show when the yearly mean alone may be used. Dr. Herbertson concludes this valuable addition to the meteorological library by giving the data he used in drawing the maps, namely a useful bibliography, and tables showing each station, latitude and longitude of each, the period over which rainfall observations have been made, the altitude, and, lastly, the mean rainfall for the period for each month.

Tierleben der Tiefsee. Von Oswald Seeliger. Pp. 49. (Leipzig: W. Engelmann, 1901.) Price 2*s*.

THIS is a popular exposition, by a well-known and thoroughly competent zoologist, of the leading features of deep-sea life and of the conditions under which it exists. It is, of course, primarily for German readers, and is evidently, and very properly, intended to direct attention to the recent German Deep-Sea Expedition. The results of the preceding "Plankton" Expedition are also referred to. The little book contains about fifty pages, of which the first thirty constitute the essay proper and the remaining twenty are notes upon paragraphs and statements in the text, and give references to the literature of the subject. In such limited space it is obvious that no exhaustive treatment is possible; many important matters are barely mentioned, and in fact the whole can only be regarded as, at most, a sketch of this large department of oceanography.

The subjects dealt with are :—depths, pressure and its effects, the distribution of temperatures, the penetration of sunlight, the deep-sea deposits, the question of food, the bipolar theory of distribution, the presence of very ancient animal types, the so-called "living fossils," and the "phosphorescence" of the sea, with some account of the light-producing organs of certain Crustacea and fishes. There is also scattered through the pages a certain amount of discussion of the characteristics and distribution of deep-sea animals.

The essay is illustrated by one coloured plate entitled "Tiefsee-Idyll," showing, not too clearly and without sufficient delicacy of detail, about twenty species of deep-sea animals belonging to various groups. It is intended to demonstrate the characteristic colours, and especially the red coloration of so many abyssal Crustacea, Echinodermata and Cœlenterata when they are brought to the surface. Both in drawing and colouring, however, the plate is rather crude, and probably gives an incorrect impression by showing so many different kinds of animals packed so close together in a very small area.

W. A. H.

A Guide to the Shell and Star-fish Galleries (Mollusca, Polyzoa, Brachiopoda, Tunicata, Echinoderma and Worms), in the British Museum (Nat. Hist.). Pp. v + 130; illustrated. (London: Printed for the Trustees, 1901.)

THIS admirable little work, written by Messrs. Smith, Bell and Kirkpatrick and sold for sixpence, may be described as the best and cheapest elementary natural history of the groups of which it treats hitherto published. A large number of excellent text-figures (some original and others borrowed from well-known works) illustrate the leading external and anatomical characters of the more important types. And although in certain places the text is necessarily somewhat technical, the diagrammatic illustrations render the meaning and application of the special terms so easily understood that every reader ought to experience little difficulty in gaining a general idea of the various groups described. This feature of the work is specially noticeable in the case of the polyzoans, whose structure often forms a stumbling-block to the beginner; and we know of no other book containing such a number of excellent figures of this group in such a small space.

The authors have not been unmindful of the economic side of zoology; and the reader will find much to interest him concerning pearls, cameos and oysters. The nomenclature has been, in the main, brought up to date, the trumpet-shell figuring as *Lotorium variegatum* in place of the familiar *Triton tritonis*, while *Scala*, instead of *Scalaria*, stands for the precious wentletrap.

A Text-book of Astronomy. By Prof. George C. Comstock. Pp. viii+391. (New York and London: D. Appleton and Co., 1901.) Price 7*s.* 6*d.* net.

IT is an excellent sign that among recent works dealing with astronomy there have been some in which methods of teaching the elementary parts of the subject have formed a notable feature. The book under notice is to be regarded as one of this class, as the author, a well-known American astronomer, has endeavoured to "concentrate attention upon those parts of the subject that possess special educational value." The importance of observations with simple appliances is strongly insisted upon in the preface, but from this point of view the book is distinctly disappointing. It is true that in the earlier chapters an attempt is made to introduce practical exercises, some of them observational and others involving the construction or study of drawings; but this admirable beginning is by no means consistently followed up. In fact, the greater part of the book does not strike us as being other than a general outline of the chief facts and principles of astronomy suitable for ordinary reading, except that at intervals the reader is expected to pause and answer a question, such as "What is the magnitude (of Algol) 43 days after a minimum?" The practical method, however, might well have been further adopted; a telescope of adequate power for the demonstration of many phenomena, such as the sun's rotation, can be cheaply and easily constructed, and graphical exercises might have been more frequently introduced with advantage. We notice, also, that the use of a globe in illustrating celestial motions is not mentioned at all. Nevertheless, so far as it goes, the practical work described will be of great value to students, and will doubtless encourage them to further efforts in the same direction.

The book touches upon nearly every branch of astronomy, and the explanations and descriptions are both concise and clear. The numerous illustrations have been selected and reproduced with great care, and, as the author remarks, are worthy of as careful a study as the text; the diagram on p. 153, illustrating the path of the moon with respect to the sun, deserves special mention.

An Introduction to the Practical Use of Logarithms. By F. G. Taylor, M.A., B.Sc. Pp. vi + 63. (London: Longmans, Green & Co., 1901.) Price 1*s.* 6*d.*

THERE can be little doubt that much time is lost by students and others who have occasion to make numerical calculations through unfamiliarity with the practical advantages of logarithms. In the present little book, however, by the consistent employment of the simplest arithmetical illustrations, the author goes far to remove the mystery in which, to many students, the subject appears to be involved by fuller theoretical treatment. The explanations are clear throughout, and these, together with the numerous carefully selected examples, should enable a student of ordinary intelligence to quickly master the use of logarithmic tables. The tables themselves occupy but six pages, two for logarithms, two for reciprocals and two for anti-logarithms. A chapter on methods of rough calculation, intended to verify the results obtained by the use of logarithms, forms a valuable addition to the book. The general subject is excellently illustrated by the application to problems in mensuration, and the whole is brought well within the range of students who have no knowledge of algebra.

LETTER TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Moon and Wet Days.

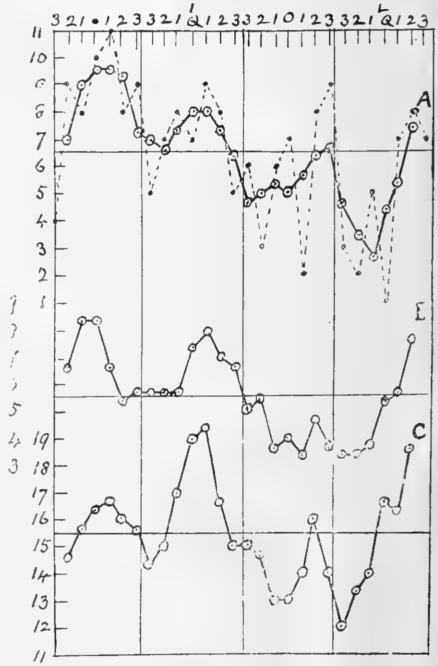
THOUGH it is counted heresy in some quarters to associate weather with the moon, the following results of a recent inquiry into the subject, whether held to be proof of lunar influence or not, might, I think, be of interest to many.

The period considered is the last 24 years. The data (which are for Greenwich) are these:—

(A) Days with ·5 in. of rain, or more, *in the year.*

(B) Days with ·4 in., or more, *in the summer half* (April to September).

(C) Days with ·2 in., or more, in the summer half.



The method in each case was first to ascertain the distribution in seven days about each of the four lunar phases (*i.e.* how often each of those 28 days had rain amounting, *e.g.*, to ·5 in., or more), then smooth the series with averages of *three.*

Both smoothed and unsmoothed curves are given in the case of A; but only the smoothed curves for B and C.

From the fact that four weeks does not quite cover the time of a synodical revolution of the moon (which is about 29½ days), there are a few wet days in each class not coming under any of the above categories. These may perhaps, with regard to the purpose of the inquiry, be left out of account. The totals dealt with are: A, 182 days; B, 158; and C, 433. These come short of the actual totals by A, 7 days; B, 8; C, 28.

Turning now to the curves, the recurrence of four long waves in the smoothed curve for A (less pronounced in C and B), may be noted, in passing, as a remarkable feature.

All the smoothed curves agree in presenting a minimum between the full moon and the last quarter (the third, second, or first day before last quarter). As to the maximum, it is about new moon in A and B, the first quarter being not much below; but in C the first quarter comes into prominence.

The salient facts of A might be put in this way. If all the wet days (182) were uniformly distributed throughout the four weeks, each group of three days would have about 20 cases of that degree of wetness (·5 in. or more). Now the lowest group (about the day before last quarter) has 8, and the highest (say about new moon) has 29, or nearly four times as many. The corresponding numbers for B are: av. 17, min. 10, max. 25; and for C, av. 46, min. 36, max. 58. The contrast becomes less marked as we lower the limit.

Individual days have some interesting features. Thus the third day before the last quarter has never, in these 24 years (summer half) had as much as ·4 in. of rain; and last quarter day has had such only once.

The data of Class A were further dealt with in this way. The odd years were treated as one group, and the even years as another. Both agreed in giving a minimum between full moon and last quarter. The maxima were about new moon in one case, and about first quarter in another.

In view of the present position of the moon-and-weather question, I content myself with merely giving these facts and inviting criticism.

It might happen that another 24 years would obliterate those distinctions, putting others in their place. Should the same relations continue in future, it would appear that in the few days before last quarter we have the best chance of escaping days which would be considered thoroughly wet.

ALEX. B. MACDOWALL.

NORTH AMERICAN FOLKLORE.[1]

ALTHOUGH the habits and surroundings of the American Indians are undergoing a gradual change through the advance of western civilisation, and their original conditions of life are disappearing, yet, thanks to American enterprise in the fields of archæology and folklore, the records of such things are being faithfully kept that they may not entirely die out or become vague tradition. It is with this object that two valuable papers on Arizona have been published in Part 2 of the "Seventeenth Annual Report of the Bureau of American Ethnology," the first dealing with the Navaho *hogáns* or houses, and the second giving an account of excavations in Arizona in 1895. The former, by Mr. Cosmos Mindeleff, contains, not only his material, but also much of the late A. M. Stephen, who lived for many years among the Navaho. The Navaho Indians now occupy a reservation of more than eleven thousand square miles in the north-eastern part of Arizona and north-western corner of New Mexico, the whole tract lying within the plateau region, and under modern conditions they are slowly developing into an agricultural tribe, although they still retain their pastoral habits. It is with the curious customs relating to the building of *hogáns* or houses by this people that the author has concerned himself, and he has elicited many interesting facts about them. The Navaho are accustomed to build two kinds of *hogán*, one for the winter and one for the summer; the former resemble mere mounds of earth hollowed out, yet they are comfortable and excellent for their purpose, and although they are of rough appearance their builders conform, not only to custom, but even to what amounts almost to ritual in their construction, with inaugural ceremonies of the most elaborate description. There is no attempt at decoration; a framework is formed of interlocked forked timbers, to which are added stout poles for the sides, and the whole is covered with bark and earth. Usually a *hogán* can be finished with the help of the neighbours in one day, and in the same evening begins the dedication. The goodwife sweeps and garners the new house, while a fire is kindled inside directly under the smoke hole. The head of the family then comes in and, after rubbing a handful of dry meal on the five principal timbers and strewing some on the floor, begins to chant the following:—

"May my house be delightful,
From my head may it be delightful,
To my feet may it be delightful,
Where I lie may it be delightful,"

and so on. The Navaho have a tradition that they were taught hut-building by the God of Dawn, while to the tribes of the plain were given skin lodges, and to the Pueblo stone houses. Long ago, when First-man and First-woman were living in the lowest Underworld, their dwelling was the prototype of the present *hogán*, and some say that instead of a covering of bark and earth its poles were wrapped in a film of sunbeams and rainbows. This Underworld was peopled by monsters who also lived in huts built after the same fashion, but of different materials. In the east dwelt *Tiéholtsodi* in a house of cloud, with Thunder guarding his door, while in the south sat the Frog in a dwelling of blue mist. The western mirage afforded a home to the Salt-woman, before whose door the Water-sprinkler dances, and towards the north the Blue Heron built himself a *hogán* of green weed with the Tortoise as his gate-porter. When mankind had ascended to the present or fourth world by the power of the Magic Reed, the kindly Dawn God taught them the methods of building that were best fitted for their several conditions. The *hogán* is but a temporary habitation, as is obvious from the following Navaho custom: When an Indian dies within a house, the beams are pulled down over the corpse while the remainder is usually set on fire, and the ruin then becomes *tabu* to the tribe for a long time to come.

The second and larger part of the volume is an account of the excavations which were carried on in 1895 by Dr. Walter Fewkes among the ruined pueblos and dwellings of Arizona. His object was to examine the ruins in the valley of the Rio Verde and the neighbourhood, as well as various other ruins, in order to solve certain problems connected with American archæology. The Moki or Hopi Indians, who now inhabit the limited area called Tusayan, claim to be descended from the pristine inhabitants of its ancient villages, and Mr. Fewkes was well fitted to conduct such investigations, having spent several summers previously among these tribes.

The ruined dwellings of the Rio Verde may be classified into three divisions. First, the pueblos, or independent habitations, that is to say those dwelling-places, ancient or modern, which are isolated on all sides from cliffs. Secondly come the cliff houses, with some part of their walls formed by the natural rock as it stands; and thirdly we find the cavate dwellings, where the rooms are excavated from the cliff wall. Dr. Fewkes carefully examined the latter class, of which so many exist on the left bank of the Rio Verde, and he considers that this side of the river in ancient times must have swarmed with people. In many of the chambers the fireplace was easily discovered, and many more had their ceilings blackened with smoke. In the neighbourhood were a few pictographs on rocks very similar to those found in Colorado, Utah and New Mexico.

Among his other explorations, Dr. Fewkes excavated part of the ruin of Awatobi, which is the connecting link between the prehistoric civilisation of Sikyatki and modern Tusayan life. It was one of the largest Tusayan pueblos in the middle of the sixteenth century, and notices of its mission occur in contemporary documents. We

[1] "The Annual Report of the Bureau of American Ethnology." J. W. Powell, Director, Washington. (Seventeenth, Part 2. 1898, pp. 277; Eighteenth, Part 1, 1899, pp. lvii+518.

find a certain Don Pedro de Tobar sent on an exploring expedition by Coronado, in the year 1540, into the province called Tusayan, which, in Coronado's letter translated by Hakluyt, is spelt "Tucano." His party consisted of about twenty men, chiefly on horseback, and when they had reached the outskirts, they hid themselves for the night under the edge of the mesa, where the Indians found them next morning armed and drawn up in line. The Indian chief scattered a handful of meal across the path, thereby meaning that they should have no passage into the pueblo; but during the parley by an accident the two parties came to blows, and the Hopi were worsted, though without loss of life. These latter then brought their conquerors presents, and Tobar here received the homage of all the province.

Both at Awatobi and Sikyatki Dr. Fewkes' diggings met with success, and he was fortunate in his discoveries. The latter place yielded up antiquities which, it is maintained, show no Spanish influence, and it is to this place we must look for the aboriginal culture of the fifteenth century. Tradition says that Sikyatki was destroyed before the advent of the Spaniards, and no mention of it can be found in documents relating to this district and period. Further, no fragment of glass or metal, or indeed anything that could give token of European civilisation, was discovered in the excavations. The pottery found at Awatobi resembles that of Sikyatki, but bears little likeness to modern ware, and the symbols used in decoration on vessels found at either of these places are very similar. Comparatively few stone axes, hammers or spearheads were found, but arrowheads were common, and many fragments of obsidian were to be seen scattered over the ruins of Tusayan. From the living rooms of Awatobi were obtained a large number of bone needles, awls and whistles, and it is probably only because the principal excavations at Sikyatki were carried on in the graves that more were not found at this latter place also. Dr. Fewkes has gone very fully into the question of the pottery, and his analysis of the markings and symbols is amplified by excellent illustrations both in black and white and in colours. The whole volume is an earnest of the increasing interest taken by Americans in the science of folklore, and future ethnologists will owe a great debt of gratitude to Mr. Mindeleff and Dr. Fewkes and their staff for their untiring energy in labouring in these fields.

Part I of the eighteenth volume contains part of the material gathered by Mr. E. W. Nelson during several years' sojourn among the Eskimos, and well bears out his statement that "the Eskimauan family or stock constitutes one of the most remarkable peoples of the world." In 1877 Mr. Nelson was stationed at St. Michael, in Alaska, and was thus able to study and observe the Eskimos of the Bering Straits until 1881, when he was appointed naturalist to an expedition to northern Siberia. His researches were continued on this expedition, and it was only through ill health that he was prevented from publishing the results of his labours immediately after his return. Even now, with the publication of this volume of more than five hundred closely-printed pages, a large section of his work remains to be elaborated.

The western Eskimos, with whom Mr. Nelson was principally concerned, inhabit an area which he calls the "Alaskan-Arctic" district, which includes the treeless coast belt, from three to one hundred miles in width, stretching from the peninsula of Alaska northwards to Point Barrow. The aboriginal inhabitants of the greater part of this tract, although separated by no physical barriers, can be divided up into well-defined groups characterised by distinct dialects. As a race they are very hardy and insensible to cold, but from exposure to damp are very liable to consumption and rheumatism, and but few live to an advanced age; in stature they vary in different tribes, some averaging no more than five feet two or three inches. Hitherto, before the arrival of traders, the land provided them with all their needs; reindeer, both tame and wild, and seal afforded most of the necessaries of life, and although wild reindeer are now being gradually exterminated, seals are still a profitable source of income. Eskimo clothes consist, for the most part, of reindeer skin, while a kind of waterproof frock is made from seal intestines. The cold, of course, necessitates the use of ear-flaps, gloves and mittens, while in the matter of personal adornment, besides tattooing, the Alaskan Eskimo wear what are known as "labrets," two small pieces of ivory, generally sickle-shaped, placed in holes specially bored for the purpose in the lower lip. Their implements and domestic utensils have been exhaustively described, but space does not allow of our going into details. We may note, however, the method of obtaining fire by the ubiquitous fire-drill, *i.e.* from the heat set up by the rapid friction of a stick against soft wood, which was in common use among the Eskimos of these regions, and the curious implements known as "snow-beaters," for beating snow from boots and clothing. Stone appears to be still very generally used for wood-cutting and skin-dressing, though the metal tools obtained from traders are now ousting the older material.

Among the fauna of these districts are to be reckoned the reindeer, mountain sheep, bear, wolf, mink, fox, lynx, beaver and marmot, but since the introduction of firearms the reindeer have woefully decreased in numbers. The Eskimos, though they have some idea of sport in some of their pursuits, have little forethought in their methods of hunting, and have sometimes killed off a whole herd of deer that has been driven into a *cul-de-sac*. On the other hand, it is held to be a test of endurance for a hunter to pursue a deer-calf on foot and run it down without shooting it, tiring it out so that it allows itself to be captured. The natives are adepts at all forms of trapping and snaring, and pass no small part of their lives in seal-stalking and tomcod-catching.

But the most interesting part of the volume is that devoted to an account of the habits, customs and traditions of this people. In Eskimo villages the centre of all social life is the *kashim*, a building essentially for men, from which women, although they frequently bring food thither, are at certain festivals rigidly excluded. It is the recognised place of oral instruction where the old men hand down the traditions of the clan to the younger generation, the sleeping place of all the unmarried men of the village, and the common house of welcome for guests. With regard to the views of moral obligation held by the Eskimos, Mr. Nelson considers that the only feeling of conscience appeared to be "an instinctive desire to do that which was most conducive to the general good of the community," which is, after all, an excellent fundamental principle of society. Stealing from the same village or tribe is regarded as wrong, but in the case of a stranger or another tribe there is no moral restraint provided the theft does not inculpate the robber's own community. Blood-feuds exist, and we find a custom very similar to the vendetta of Corsica and Sardinia prevalent among the Eskimos, and it is a commonplace among them that a man who has committed a murder may easily be recognised by the restless and watchful expression of his eyes. Marriages are sanctioned in various ways. Among the Unalit, when a young man falls in love he leaves his parents to arrange matters with those of his inamorata, and then, arrayed in his best, goes down to her house and, after presenting her with a new trousseau, leads her home. Burials vary in different places: at St. Michael the dead are buried in a sitting posture with the knees drawn up, while on the

Lower Yukon the position of the corpse is similar, but the head is forced forward between the knees. At Cape Vancouver exist certain memorial image-posts of driftwood, set up near the sea, either representing the human figure or with a rude representation of some totem on the top, which are said to be monuments to those who have died either in landslides or at sea, and whose bodies have never been recovered. Among certain tribes a great Feast to the Dead is celebrated, extending over five days. It is the usual thing, when a person dies, for the next of kin to present food, drink and clothing to the departed spirit, through the medium of the dead person's namesake, at the first festival to the Shades after the death takes place. For some years this continues, the men in the village each giving to their ancestors offerings of various kinds, which are saved up by the chief mourners, in whose hands they are deposited, until it is considered that the village possesses a sufficient hoard of gifts to admit of a Great Festival being held. A certain date having been fixed upon, a kind of summons is issued to the Shades at the next minor festival; invitation stakes, decked with the totems of each departed spirit, are planted before their graves, and songs of invitation are sung. After the observance of this great feast, which Mr. Nelson describes in its entirety, an Eskimo is held to be exempt from further rites and duties to the dead until another near relation dies, when the process begins again.

The Eskimos, from the Kuskokwim River northward, have a regular system of totem marks. Mr. Nelson tells of a villager on the Lower Yukon who explained the totems to him thus: "All of our people have marks which have been handed down by our fathers from very long ago, and we put them on all our things." For instance, among the clan which bears the wolf totem the men fasten a wolf tail to their belts, while the women twine pieces of wolfskin in their hair, and it is customary among them to mark their weapons with their totem, that thereby (according to the author) they may assume the qualities of such animals and become especially deadly. With regard to the adoption of totems we may notice the following story, told by a villager whose sign was a red bear. Once upon a time one of his ancestors, who was a celebrated hunter, while out one day after small game with only blunt arrowheads in his quiver, came across a large red bear. Nothing daunted, however, he let fly arrow after arrow, and—so runs the tale—having succeeded in breaking all its bones, killed it. From that time forth he and his descendants used the red bear as their totem.

In the cosmogony of the Eskimos it is held that the earth was created by the Raven-Father, who is said to have come from the sky and fashioned it when everything was a watery chaos. Now although the earth had been formed, it was as yet devoid of inhabitants, and for the first four days Man lay ensconced in the pod of a beach-pea. On the fifth day he burst the pod and came forth a fully developed Man, and while he was still looking about him the Raven flew up. "Where have you come from?" says the Raven; and the Man points to the empty shell of the pea. "Ah!" replies the Raven, "I made that vine, but never expected that anything like you would come forth from it." So he takes Man away and shows him how to satisfy his hunger with berries. Like other animals in the stories, the Raven possesses the power of assuming human form by the simple process of pushing up his beak like a mask, and during his colloquy with Man has availed himself of this. The Raven then fashions some reindeer in clay and, drawing down his mask, waves his wings four times over them and they at once receive life; but as they were only dry in spots when they came into existence, their skins are dappled and they become the tame reindeer of semi-domesticity. A pair of wild reindeer are also formed, and while the bellies are allowed to dry white, the remainder is kept moist, and by this means the wild reindeer, which to this day are of a light colour only underneath, are brought into being. Then the Raven thinking of Man's loneliness, retires a short distance and moulds an image in the shape of Man, fastening a long tuft of grass at the back of the head for hair. With a wave of the Raven's wings as before, the clay doll is transformed into a beautiful young woman, who in a short time bears the Man a child. They take the child to the riverside and smear him all over with clay, and in three days he becomes a full-grown man.

One day Man asks the Raven about the sky, and at his request the Raven takes him up to heaven and shows him the land he has made there—a beautiful country peopled by a small race—and after being made welcome there he returns through a star-hole to earth. But after a time the Man hungers to return to the little people in the sky, and he goes up again with the Raven. During his absence, however, the earth-people increase so that the animals are in danger of extermination, and this rouses the anger of both Man and the Raven. So they catch ten reindeer, which at this time have long, sharp teeth, and let them loose one night on earth to ravage and destroy. For two nights these fearful beasts attack houses and destroy the inmates, but on the third the villagers bedaub their walls with a paste made of fat and berries, so that when the wild herd again begin to batter the walls with their teeth, the sour berries cause them to rush about shaking their heads so violently that finally all their sharp teeth drop out, and this is the reason that all reindeer teeth are now small and harmless.

Another quaint story is the tradition which explains the reason why the women in the north are deft with the needle, while those of the south dance so nimbly. Long ago the northland was inhabited by men only and no woman had come among them; but it was noised abroad that far away in the south one woman dwelt alone. So one day one of the northerners set his face southward and journeyed until he reached the woman's dwelling, and in course of time he married her and congratulated himself that he had a wife while the son of the headman of the north was still a bachelor. But meanwhile this same bachelor was travelling south with like purpose, and he came on the house while the man was talking within, and, hiding himself, waited until night fell. Then he forced a way in, and, seizing the woman, began to drag her away; but the noise awoke the husband, who leapt forth and grasped his wife's feet as she was being dragged through the door. Both men pulled violently and to such effect that the poor woman's body was torn in half, and the robber went off home with the upper part, while the legs were left behind. Then the rightful husband carved a body of wood and fastened it to the legs, and the other man completed his half in a similar way, and as soon as they had finished, each addition received life, and out of one woman were made two. But although the woman of the south could dance featly, her wooden fingers prevented her from embroidering; and the woman of the north, by reason of her wooden legs, excelled only in needlework, and it is from these two that the women of the north and south sprang, inheriting their several characteristics.

With this story we must take leave of Part I. Mr. Nelson has done his work excellently, and the matter has been arranged in a careful and scientific manner. The Bureau of American Ethnology is greatly to be congratulated, both on the indefatigable workers whose services it has secured and on the excellent way in which it has published their researches. We shall look forward to the remainder of Mr. Nelson's work on the Eskimos with interest.

SOME SCIENTIFIC CENTRES.

II.—THE LABORATORY OF WILHELM OSTWALD.

THE year eighteen hundred and eighty-seven is memorable in the history of physical chemistry; it witnessed the publication of van 't Hoff's discovery of the identity of the laws of gases with those of dilute solutions; and it was the year in which Arrhenius in a classic memoir enunciated his theory of electrolytic dissociation; for the University of Leipzig it had a special significance, as it was then that Ostwald succeeded Wiedemann in the chair of physical chemistry and founded, with van 't Hoff, the *Zeitschrift für physikalische Chemie.* Heidelberg, it is true, had been the first to devote a special chair to the new subject, and Kopp had held it from 1864; but Kopp devoted his time almost entirely to research, and it remained to Wiedemann, who, in 1871, was appointed to the newly created chair at Leipzig, to institute a school for the investigation of these new problems. In 1887 he gave place to Wilhelm Ostwald, confining himself thenceforth to the study of pure physics, of which he had been made professor.

Ostwald was born in Riga on September 2, 1853; at an early age he devoted himself to the study of physics and chemistry at the University of Dorpat, where he "*habilitierte*" in 1878. After teaching there for two years he was made "ordentlicher Professor" at the Riga Polytechnic, which position he held until called to Leipzig in 1887.

The Leipzig laboratory, in which he worked until 1897, was situated in the "Landwirtschaftliche Institut," an old pile originally devoted to agricultural chemistry, and in every way unfitted for the carrying on of those delicate experiments which brought Ostwald to the forefront of scientific workers. Research was carried on under countless difficulties; the light was bad, the rooms unventilated, the heating effected by means of stoves difficult to regulate and producing dust which caused much injury to the finer instruments; no precautions had been taken in laying the foundations to ensure the deadening of vibrations; thus many experiments were ruined; the lack of space precluded the use of telescopes for reading scales, and altogether it would have been difficult to construct a laboratory worse adapted for physico-chemical investigations. But in spite of all these drawbacks the laboratories were soon overcrowded, and additional benches had to be fitted up in the corridors and cellars to accommodate the increasing numbers.

FIG. 1.—Ostwald and van 't Hoff. (Taken in Ostwald's private laboratory.) The illustration shows the two investigators standing by Prof. Ostwald's apparatus for automatically registering on a strip of paper the peculiar phenomena attending the solution of metallic chromium in acids.

(The author of this article begs to acknowledge his indebtedness to Mr. C. W. Foulk, who kindly placed this most interesting photograph at his disposal.)

In 1897 the University and the Saxon Government gave proof of their appreciation of the importance of the new science and of Ostwald's services by placing at his disposal a new specially erected Physico-Chemical Institute, equipped with all the accessories that modern ingenuity has devised.

The work of Ostwald is intimately associated with the theories of van 't Hoff and Arrhenius. In an address delivered in 1891 before the sections of physics and chemistry at the yearly meeting of the German men of science, Ostwald described what his own and the general attitude was towards the views put forward by these two men.

"The consequences connected with van 't Hoff's discovery being so important and wide-reaching, it had in general a friendly reception, though a few scientific men attempted a slight resistance. . . . All the uneasiness connected unavoidably with important revolutions had been directed against a second idea, which, appearing somewhat later, removed a fundamental difficulty in the theory of solutions, which had until that time made its acceptance impossible for me. This idea has nevertheless shown itself as an aid to investigation to be of unparalleled sweep and value; it is the theory of electrolytic dissociation of Arrhenius. . . . No scientific idea produced in my time has helped me in such measure as these two theories. . . . In particular the extraordinarily manifold and severe test, which lies in the numberless numerical consequences of the theories in all possible fields, has yielded such a number of confirmations that the relatively rare cases where the unprejudiced decision was insufficient entirely vanish."

In 1867 Guldeberg and Waage published their investigations on the subject of mass action, and enunciated the law that the intensity of the interaction of two substances was proportional to the product of their active masses, and to a coefficient which depended on the nature of the substance, temperature, &c.

This induced Ostwald, in 1877, to carry out a long series of experiments with the object of determining, by volumetric and optical methods, the manner of distribution of a base among different acids present in excess, and hence calculate the "specific affinity coefficients" of the latter.

In 1884 he suggested another method for the determination of these coefficients; it consisted in measuring the velocities of reactions induced by them, such as the inversion of cane sugar, the decomposition of acetamide, methyl acetate, &c. The results he obtained in this way were found to confirm generally those obtained in the previous series of experiments, as a comparison of the numbers in the subjoined table shows:—

		Velocity Constants.	
	Avidity.	Sugar Inversion.	Decomp. of Acetate.
Hydrochloric	100	100	100
Nitric	100	100	91·5
Sulphuric	49	53	54·7
Oxalic	24	18·6	17·4
Orthophosphoric...	13	6·2	—
Monochloracetic	9	4·8	4·3
Tartaric	5	—	2·3
Acetic	3	0·4	0·35

In 1887 came the theory of electrolytic dissociation; it explained at once the relationship which had been observed both by Arrhenius and by Ostwald between the affinity coefficients and electric conductivities; the degree of dissociation of an acid being a measure of its strength, and the conductivity being due principally to the hydrogen ions, it would follow from theoretical considerations that the conductivities of solutions of different acids would be proportional to the number of hydrogen ions in the solution, and so to the relative strength of the acid. Ostwald pointed out that the application of Guldeberg and Waage's law to electrolytes should enable us to obtain a "dissociation constant" for each electrolyte, the determination being made by means of conductivity measurements.

He then proceeded to trace the relationships between the "dissociation constants" of organic acids and the structure or constitution of the radicals. He showed that they varied with the nature of the acid radical, and that an increase of the negative group such as O, Cl, Br, I, CN, &c., increased the tendency of the hydrogen

FIG. 2.—Ostwald and Arrhenius.

ion to split off, while an increase of the positive radical, such as H, NH_2, &c., decreased this tendency.

The theory of electrolytic dissociation was further extended by Ostwald to explain the colours of solutions; he found that the absorption spectra of dilute solutions of different salts with similarly coloured ions are identical. In conjunction with Nernst he investigated the absorption spectra of a number of salts of permanganic acid, fluorescein, eosin, &c., and confirmed the corollary of the theory of Arrhenius; the colour of a dilute solution of a salt was thus shown to depend on the colour of the free ions present in the solution, the absorption of a completely dissociated electrolyte being the sum of the absorptions of the positive and negative components.

In 1897 he collected and published in four volumes the more important investigations which had been carried on during the previous ten years under his direction; they included work in nearly every department of physical chemistry; among them were the famous experiments on the theory of the electrical charges of ions; Beckmann's original papers on the theory and use of the ebullioscope and crioscope; Nernst's classical memoir on the osmotic origin of currents, and many other important contributions to our knowledge of electro-chemistry, the theory of cells, polarisation and contact electricity.

But Ostwald's labours have not been confined purely to research. In addition to his great efforts in the development and propagation of the new views on solutions and electrolytic dissociation, his name is associated with a number of treatises of varying scope, all stamped with his own originality. In 1885–1887 appeared his famous "Lehrbuch der allgemeinen Chemie"; and two years later his "Grundriss," which has since passed through three editions and been translated into several languages. In the "Grundlagen der analytischen Chemie" (1894) he approached the subject from an entirely new standpoint, while his "Grundlinien der anorganischen Chemie" (1900) bids fair to become one of the standard text-books.

Prof. Ostwald has told us how, more than fifteen years ago, he and his friend Arrhenius, walking along the banks of the Mälarsee, tried to picture the then nebulous future of physical chemistry. In 1887 the new science had so far advanced that he was able, with the assistance of van 't Hoff, to found a journal to be devoted entirely to it, the *Zeitschrift für physikalische Chemie*. The progress which it has since made has gone far to justify even the wildest hopes; and to that progress few have contributed more than the present director of the Leipzig Institute.

F. H. N.

THE DEVELOPMENT OF CHEMICAL RESEARCH.[1]

IF Justus Liebig had no other claims on the gratitude of posterity, we should still be indebted to him for the part which he played in emphasising the value of chemistry as an educational factor. He it was who first showed the importance of practical work in any scheme of scientific training; and, as Kolbe has pointed out, it was from the Giessen laboratory that that system emanated by which a student commenced with qualitative exercises, passed on to quantitative analysis, then to a series of preparations, leading up finally to independent research. Liebig's success in stimulating pupils to original thought is evident from a brief survey of the classical memoirs that were worked out in his laboratory, and of a few of the more illustrious of his numerous "schüler," including as they did such names as A. W. Hofmann, Strecker, Fresenius, Playfair, Williamson, Wurtz and Frankland.

[1] "A Select Bibliography of Chemistry, 1492–1897." By Henry Carrington Bolton. Section viii. Academic Dissertations. Pp. iv+534. (Published by the Smithsonian Institution, City of Washington, 1901.)

The Giessen methods were at once adopted in the several laboratories which began to arise towards the close of the earlier half of the nineteenth century—at Göttingen in 1836, under the direction of Wöhler, and later at Marburg and Leipzig, by Bunsen and Erdmann. They have been accepted by all the great teachers who followed after, from Kolbe, Kekulé and Wislicenus to Victor Meyer, Hantzsch and Curtius; and they are in vogue to-day, not only throughout Germany, but in nearly every country where chemistry is taught. Germany, however, had a long start; in France it was not till the end of the late 'sixties that Wurtz succeeded in persuading the Government of the necessity for reform in the methods of scientific training; and in Great Britain, although the College of Chemistry—the present Royal College of Science—was founded as early as 1845, it is only comparatively recently that public attention has been aroused to the inevitable result of continued apathy.

The publication of the eighth section of Mr. Bolton's laborious compilation, "A Select Bibliography of Chemistry," the first volume of which appeared in 1893, completes the undertaking begun in 1888; the entire work contains rather more than 25,000 entries. In such a vast undertaking as this, omissions are unavoidable; the collection of titles for a fourth volume is, however, in progress, and will afford an opportunity for making the list more complete.

The present volume, as its title indicates, is devoted exclusively to academic dissertations; it is not intended to serve as an index to the chemical memoirs that have appeared in periodicals, but only as a list of those that have been printed independently, the Russian titles being contributed by Prof. A. Krupsky, of St. Petersburg.

An analysis of the contents reveals the fact that during the period covered by the bibliography, namely from 1492 till 1897, no less than 4800 theses on chemical subjects have been handed in at German universities; allowing for omissions, the correct number would probably be considerably more than 5000.

France comes next on the list with a total of, roughly, 1500. Switzerland follows with 600, and Russia with 120; the other countries are all below 100.

When we remember that Germany has some twenty-two universities with splendidly equipped laboratories, maintained either completely or in part by the Government, not to mention the numerous technical colleges, these figures are not to be wondered at.

A better idea of the respective outputs as regards research of these different countries may be gathered from the fact that Germany has six periodicals devoted to the publication of pure chemical research; these are the *Annalen*, the *Berichte*, the *Journal für practische Chemie*, the *Zeitschrift für physikalische Chemie*, the *Zeitschrift für analytische Chemie* and the *Zeitschrift für Chemie*. France has the *Annales de Chimie et de Physique* and the *Bulletin de la Société Chimique*; a certain number of chemical memoirs appear also in the *Comptes rendus*; the other countries are represented chiefly by the journals of their respective societies.

Looking back over her record, Germany may well be proud of those illustrious teachers who did so much to build up her educational system; the rapid strides of German industries in recent years pay eloquent testimony to the success and value of their efforts. At the present time in England the Government is at last waking up to the necessity for action; the growth of technical schools throughout the country is a move in the right direction. But much still remains to be done. Research in every department of science must be stimulated at all costs, and British manufacturers must abandon their old empirical methods. A "research chemist" is worth more than eighty pounds a year, and we must at last realise that the spirit of economy may be carried to fatal excess. The outlook is far from cheerful, and so long as the development of research is entrusted to indifferent and irresponsible authorities it is difficult to hope for better things. Scientific discoveries may not increase the beauty of the earth, but we live in a practical age and must be practical. To be lulled by a sense of false security is to commit national suicide.

INTERNATIONAL ENGINEERING CONGRESS.

THE International Engineering Congress to be held at Glasgow from Tuesday to Friday next week, September 3-6, will be an important congregation of representatives of all branches of engineering practice. The Congress may almost be regarded as a federated meeting of technical societies, for seven of the nine sections are in charge of such organisations. The suggestion that technical societies should hold simultaneous meetings this year in Glasgow was made by the Institution of Engineers and Shipbuilders in Scotland, and it developed into the scheme for an International Engineering Congress.

Lord Kelvin has accepted the honorary presidency of the Congress, and Mr. James Mansergh, F.R.S., is the president. Mr. Mansergh will deliver a short address on Tuesday, and the members will afterwards meet in their respective sections in the University buildings. A large number of papers are to be read, and among them several of scientific interest. The following is a list of the sections, and of a few of the subjects to be brought forward for discussion :—

Section I.—Railways.—Chairman, Sir Benjamin Baker. The economy of electricity as a motive power on railways at present driven by steam, by Prof. C. A. Carus-Wilson.

Section II.—Waterways and Maritime Works.—Chairman, Sir John Wolfe Barry, K.C.B., F.R.S. Novel plant employed in transporting the excavations on the Chicago Drainage Canal Works, by Mr. Isham Randolph ; the improvement of the Lower Mississippi by the Mississippi River Commission, by Mr. J. A. Ockerson ; irrigation in the Nile Valley and its future, by Mr. William Willcocks, C.M.G.; recent improvements in the lighting and buoying of coasts, by Mr. D. Stevenson, and by Baron de Rochemont.

Section III.—Mechanical Engineering (Institution of Mechanical Engineers).—Chairman, Mr. W. H. Maw. Effect of temperature on cooling water in high speed automobiles, by Prof. H. S. Hele-Shaw, F.R.S. ; trials of steam turbines for driving dynamos, by the Hon. C. A. Parsons and Mr. G. Gerald Stoney ; application of metric system to workshops, by Mr. Arthur Greenwood ; power required to drive marine engine works and for electric lighting, by Mr. James Crighton and Mr. W. G. Riddell.

Section IV.—Naval Architecture and Marine Engineering (Institution of Naval Architects).—Chairman, the Right Hon. the Earl of Glasgow. The chief characteristics of the naval development of the nineteeth century, by Sir Nathaniel Barnaby, K.C.B.

Section V.—Iron and Steel (Iron and Steel Institute).—Chairman, Mr. William Whitwell. Report on the nomenclature of metallography, by the committee of the Iron and Steel Institute ; on the spectra of flames at different periods during the basic Bessemer blow, by Prof. W. N. Hartley, F.R.S., and Mr. Hugh Ramage ; on iron and copper alloys, by Mr. J. E. Stead.

Section VI.—Mining (Institution of Mining Engineers).—Chairman, Mr. James S. Dixon. Presidential address, by Sir William Thomas Lewis, Bart. ; alternating currents, and their possible application to mining, by Mr. S. F. Walker ; a new diagram of work, by Mr. H. W. G. Halbaum.

Section VII.—Municipal Engineering (Incorporated Association of Municipal and County Engineers).—Chairman, Mr. E. George Mawbey. Research into the system of sewage purification by bacterial and other methods, by Mr. K. F. Campbell ; treatment of sewage, by Lieut.-Col. A. S. Jones, V.C. ; sewage disposal, by Mr. A. B. M'Donald.

Section VIII.—Gas Engineering (Institution of Gas Engineers).—Chairman, Mr. George Livesey. Electrolysis of gas pipes, &c., by Dr. Leybold ; water gas as an adjunct in the manufacture of coal gas, by Prof. Vivian B. Lewes ; Emile Gobbe's process for the production of water gas, by Mr. Fernand Bruyere.

Section IX.—Electrical (Institution of Electrical Engineers).—Chairman, Mr. W. E. Langdon. Electricity supply meters of the electrolytic type, by Mr. J. R. Dick ; Kelvin's electric measuring instruments, by Prof. M. Maclean ; continuous-current dynamo design, by Mr. H. A. Mavor ; the use of electricity in the propulsion of road vehicles, by Mr. A. R. Sennett.

Advantage will be taken of the presence of a large number of engineers in Glasgow to open the new "James Watt Engineering Laboratories." These laboratories are being erected and equipped at a cost of more than 40,000*l.*, the funds being raised partly by subscriptions from the citizens of Glasgow and neighbourhood, partly by a grant of 12,500*l.* from the Bellahouston Trust, and the remainder from funds already at the disposal of the University Court. Lord Kelvin will preside at the opening.

Arrangements have been made for visits to works of interest to members of all branches of engineering, and for a number of excursions. There will also be a banquet, a reception by the Lord Provost, and a ball, so that the social aspects of the Congress are pleasing to contemplate. These pleasures, combined with the meetings of the sections and visits to the International Exhibition, should make the Congress memorable to all who take part in it.

NOTES.

THE seventieth birthday of Prof. Eduard Suess, who for more than forty years has occupied the chair of geology in the University of Vienna, and is universally regarded as the greatest of living geologists, has called forth hearty greetings from all parts of the world. Prof. Suess was born in London on August 20, 1831, his father being at that time a merchant in the City ; but, while a sympathetic friend of England, he has always remained a true Austrian, and his life-work as geologist, palæontologist and politician has been carried out in his own country. His researches, while largely palæontological, have covered a wide range, and they have led him to grasp more fully than others the problems in the ancient physical geography of the earth, which he dealt with in his brilliant work, "Antlitz der Erde." As remarked by a correspondent in the *Times*, Prof. Suess, to his own countrymen, "has been much more than a distinguished pioneer in science. He has been a living example of enlightened patriotism and devotion to the public welfare, and an indefatigable reformer, whose works will long remain a monument to his memory."

AMONG the many objects that attracted attention during the recent meeting of the International Congress of Zoologists at Berlin, few were more noteworthy than a large mounted adult male gorilla, exhibited by Herr Umlauff, of Hamburg. This specimen is remarkable not only for its size, which rivals, if it does not exceed, that of any example of the gorilla previously obtained, but also because its exact history is known. It was shot by Herr H. Pascen, of Schwerin, the representative of a Hamburg mercantile firm, in Yaunde, in the interior of the German Colony of Kamerun, about fifteen days' journey from the coast, on April 15, 1900. It has been hitherto generally believed that the gorilla is only to be found in Gaboon and the adjoining districts of French Congo immediately under the Equator; but it now appears that the range of this Anthropoid Ape extends further north into the interior of Kamerun. The specimen in question has, as we are informed, been acquired by Mr. Walter Rothschild for the Tring museum.

THE fifth International Congress of Criminal Anthropology will be held at Amsterdam on September 9–14.

THE death is announced of Admiral de Jonquières, who became a membre libre of the Paris Academy of Sciences in 1863, and was renowned for his works in geometry.

IN addition to the papers already mentioned to be read before the Zoological Section at the forthcoming meeting of the British Association, it is hoped that Mr. J. Stanley Gardiner will give an account of his recent researches upon the coral islands of the Maldives.

A REMARKABLE discovery of Palæolithic implements has lately been made on the estate of the Marquis of Ailesbury, at Knowle Farm, on the borders of Savernake Forest. Between 200 and 300 implements (according to a report in the *Times*) have been obtained from a pit which has been opened in a high-level valley gravel. The implements, which are mostly made of flint, have been well fashioned, and some have been finely polished, as if from the effects of blown sand. They include forms familiar from the Somme valley, and also from Hoxne and other places in this country.

THE new milk standard adopted by the Board of Agriculture will come into force on September 1. The regulations state that when a sample of milk (not being sold as skimmed, or separated, or condensed milk) contains less than 3 per cent. of milk-fat, or 8·5 per cent. of milk-solids other than milk-fat, it will be presumed for the purposes of the Sale of Food and Drugs Act, 1875 to 1899, until the contrary is proved, that the milk is not genuine. Where a sample of skimmed or separated milk (not being condensed milk) contains less than 9 per cent. of milk-solids, it will be regarded as not genuine.

THE death of Dr. Adolf Fick, late professor of physiology at the University of Würzburg, is announced in the *Times*. Dr. Fick was born at Cassel in 1829, became professor of physiology at the University of Zurich in 1856, and in 1868 was called to the chair of physiology at the University of Würzburg, a position that he held until his retirement a few months ago. Among his published works may be mentioned a treatise on medical physics, 1857, which passed through many editions; a compendium of physiology, 1860 (third edition 1882); "Anatomy and Physiology of the Senses," 1862; "Mechanical Work and the Production of Heat during Muscular Action," 1882; "Ursache und Wirkung," 1882; "Versuch über die Wahrscheinlichkeiten," 1883. Prof. Fick was also an active contributor to the leading scientific reviews, and furnished many important papers to the records of his University.

THE Paris correspondent of the *Lancet* announces that legal authority has just been given for the creation of a fund for scientific research. It is divided into two sections, and its object is the promotion of purely scientific work relative (*a*) to the discovery of new methods of treatment of the diseases which attack man, domestic animals, and cultivated plants; and (*b*) to the discovery, apart from the medical sciences, of the laws which govern natural phenomena (mechanics, astronomy, natural history, physics, and chemistry). The income of the fund will be derived from the following sources:—(1) Grants made by the Government, by the departments, by the communes, by the colonies, and by other sections of the population. (2) Gifts and bequests. (3) Individual or collective subscriptions. (4) Grants deducted from the portion of the proceeds of the *pari-mutuel* assigned to philanthropic or charitable purposes locally; the annual amounts of these grants, which will not be less than 125,000 francs (5000*l.*), will be fixed each year on the application of the council of management by the special commission held at the Ministry of Agriculture. (5) Interest of money invested in Government securities or deposited with the Treasury. The fund is subject to the authority of the Ministry of Public Instruction, and is managed by a council assisted by a technical commission concerned with the grants.

THE New York Board of Health has distributed a circular of information, prepared by Dr. H. M. Biggs, upon the cause and prevention of malarial fever. This course has been taken because malarial fever is prevalent in certain boroughs of New York City, and is likely to extend on account of the extensive excavations and consequent formation of rain-pools in various parts of these boroughs, if means are not employed for its prevention. The circular states that the following simple precautions suffice to protect persons living in malarial districts from infection:—(1) Proper screening of the house to prevent the entrance of the mosquitoes. The chief danger of infection is at night, inasmuch as the Anopheles bite mostly at this time. (2) The confinement and continuous screening of persons in malarial districts who are suffering from malarial fever. (3) The administration of quinine in full doses to malarial patients to destroy the malarial organisms in the blood. (4) The removal of the breeding places of the mosquitoes through drainage, filling up of holes and surface pools, and emptying of tubs, pails, &c., which contain stagnant water. (5) In pools which cannot be drained or filled, the destruction of the mosquito larvæ by the use of petroleum thrown upon the surface, by the introduction of minnows and other small fish which eat the larvæ, or by both methods.

THE removal of the astronomical instruments from the Observatory at Pekin, as a part of the German loot, has already been mentioned in these columns. No particulars of the action have come under our notice, but the right of Germany to the instruments has just been questioned, so that the subject is still under discussion.

WITH the intention of directing attention to the cultivation of the vine in the colonies, Sir James Blyth, Bart., contributes to the *Chamber of Commerce Journal* for September an instructive article upon vine culture. His remarks upon the value of scientific investigations in connection with the industry are of interest. It is pointed out that owing to the invasion of phylloxera, and the consequent scientific discoveries for its prevention or extermination, labour on the vineyards has become continuous throughout the year. It is a common remark amongst the present proprietors of the Médoc, that in their fathers' time the vines were simply pruned, the land ploughed four times a year, and the grapes gathered at the vintage, leaving all else to nature and the seasons. Now, from the moment the grapes are gathered, scarcely a week—certainly not a month—passes, but some process for the defence of the roots, the stems, or the leaves takes place. The greater care exercised in planting, and the experience acquired in combating all the enemies to the well-being of the vine, promise not only to conquer these insidious fungoid and insect pests, but vastly to increase the proportional productivity of the areas under vines. For instance, there has been a considerable increase in the fecundity of the vine since steps have been taken to regenerate the vineyards which have been affected by phylloxera. This may be judged by the fact that, whereas in 1875, which, as is well known, was a record year in France for quantity as well as quality, an exceptional average yield of 294 gallons per acre was produced, the average yield in 1900 was as much as 343 gallons per acre.

PROF. OTTO NORDENSKJÖLD is at Malmö, Sweden, making arrangements for his South Polar Expedition. A Reuter message says he has made the following statement to a Press representative as to the plan and object of his expedition :—"As soon as the *Antarctic* returns from the expedition which she has made to Spitsbergen for meridian measurements, we start from Göteborg, certainly not later than October 1. From Göteborg we shall proceed to England, and thence to Buenos Ayres and Tierra del Fuego, whence we shall make our way to the Antarctic regions. We shall endeavour to push as far south as possible with the *Antarctic;* and, when winter comes on, we shall send a party on shore to winter. That party will probably consist of six persons, of whom I shall be one. We shall build a small hut for ourselves, and engage in meteorological, magnetic, hydrographic, and other scientific observations. As soon as we have landed, the *Antarctic* will return to Tierra del Fuego ; and a scientific observer, who will sail with her, will conduct the researches in that hitherto little explored country. In this way we shall be able to work in two detachments, and make as much use of our time as possible. Prof. Ohlin, of Lund, and M. K. A. Andersson will accompany me as zoologists. Dr. Bodman will come as hydrographer and magnetician, M. Skottoberg as botanist, and Dr. E. Ekolof as medical officer. Captain Larsin, who has already made several voyages to South Polar regions, will be in charge of the *Antarctic.*"

FROM a note in the *Times* we see that the British Consul-General at Marseilles reports that artificial indigo is killing the natural product on the French market. The artificial dye already regulates prices. The Badische Company have for two years been making indigo near Lyons for local consumption, while the Höchst Farbwerke are manufacturing synthetic indigo by another process in the same city. Artificial indigo is classed for Customs duty with natural indigo, and, since goods dyed with it are not required to be declared as such, they are sold at similar prices to goods dyed with natural indigo. Lyons dyers of cotton and woollen goods and Lyons dealers in indigo say that natural indigo has been ousted from many dye works, especially since artificial indigo has been prepared by crushing. Small dyers favour synthetic indigo, because they can buy small quantities as required and prices do not violently fluctuate. But, as the vegetable dye gives more solidity to the cloth, it is still likely to be used for military uniforms. Dr. Calmette, of Lille, is said to have patented a process for extracting indigotin from vegetable indigo up to thrice the quantity produced by the more primitive methods. It is curious that the Bengal Chamber of Commerce have recently had to ask the Havre Chamber to abolish a rule under which indigo tendered in that important terminal market must be guaranteed to be manufactured by the "old" process—a serious restriction in view of the many new processes recently introduced. The request has been complied with, and certificates will not be needed after April 1 next. From the Consular report on Frankfurt-on-Main for 1900 it appears that the Badische Company has borrowed 12,000,000 marks for the purpose of enlarging the production of artificial indigo and reducing its cost price. The company now claims to be able to supply one-sixth of the world's requirements. The Höchster Farbwerke are also extending their indigo business. Natural and artificial indigo are both 10 per cent. cheaper than last year, the policy of manufacturers being to keep the price of the synthetic rather below that of natural indigo.

A BUST of Dr. G. Armauer Hansen, the discoverer of the leprosy bacillus, was unveiled a few days ago by Prof. Visdal in the garden of the Museum at Bergen, in the presence of many Norwegian and foreign medical men. We learn from the *British Medical Journal* that an address was delivered by Prof. O. Lassar, of Berlin ; and Drs. Sandberg and Lie, of Bergen, also spoke. Congratulatory messages were sent from all parts of the world, and a letter from Prof. Virchow was read, in which the veteran pathologist, after expressing his regret at his inability to be present, went on to say that Dr. Hansen's work had definitively cleared up a large and difficult field of pathology, and that his name was known and celebrated throughout the whole world as a benefactor of mankind. Dr. Hansen was born in Bergen in 1841, and received his early education in the cathedral college of that town. His first investigation was to work out the significance of the so-called globi, or leprous cells of Virchow, and the results of his observations were published in 1869. He then obtained evidence of the contagious and specific nature of the malady, and the Medical Society of Christiania voted a sum of money for him to continue his research. Further investigations of the peculiar bodies (globi-brown corpuscles) previously referred to were rewarded by the discovery, in unstained preparations, of bacilli which were ultimately stained and proved to be the bacilli of leprosy. This discovery was made in 1873—that is, about ten years before the bacillus tuberculosis was made known to the world by Koch. For years Hansen has repeatedly tried to cultivate and inoculate the *Bacillus leprae,* which is known as Hansen's bacillus, but up to the present fruitlessly. One great point, however, has been gained—namely, that it is now practically admitted by all those engaged in the study and observation of leprosy, that the disease is contagious. In Norway, practical legislation on this basis has given the best results, and leprosy there is gradually and surely diminishing. Dr. Hansen celebrated his sixtieth birthday on July 29, and the tribute to his lifelong work and devotion above recorded will be gratifying to all lovers of science. The King of Norway has conferred upon him the distinction of Commander of the Order of Ola.

A LIST of nearly fifty papers accepted by the committee of Section A of the British Association, for reading at the forthcoming meeting at Glasgow, has been received since the publication of the forecast of the work of the other sections in last week's NATURE. Arrangements have been made for discussions on optical glass, to be opened by a paper by Dr. R. T. Glazebrook, F.R.S. ; energetics, to be opened by Dr. J. Larmor, F.R.S., with a paper on the relation of energetics to molecular theory ; and on the proposed new unit of pressure, to be opened by Dr. C. E. Guillaume. A report will be received from the committees on tables of certain mathematical functions, underground temperature, and the determination of magnetic forces. Lord Kelvin will read papers on the absolute amount of gravitational matter in any large volume of interstellar space, and on "Aepinus atomised." Prof. A. Gray, F.R.S., will read several papers, among the subjects being the influence of a magnetic field on the viscosity of magnetisable solids and liquids, elastic fatigue, and induced currents produced by starting a convection current. The following are among other physical papers :—On a new instrument for magnetic work on board ship, by Captain E. W. Creak, F.R.S. ; on the effect of sea temperature on the seasonal variation of air temperature of the British Isles, by Mr. W. N. Shaw, F.R.S. ; the law of radiation, by Dr. J. Larmor, F.R.S. ; the Michelson-Morley effect, by Prof. W. M. Hicks, F.R.S. ; sur les effets magnétique de la convection électrique, by Dr. V. Crémieu ; on the magnetic field due to the motion of a charged condenser, by Dr. F. T. Trouton, F.R.S. ; on resolving power in the microscope and telescope, by Prof. J. D. Everett, F.R.S.; on the interference of light from different sources, by Dr. G. J. Stoney, F.R.S. ; on a simple method of accurate surveying with a hand camera, by Prof. H. H. Turner, F.R.S. ; on the conduction of electricity through mercury vapour, by Prof. A. Schuster, F.R.S. ; hydrostatic pressure, by Prof. W. Ramsay, F.R.S. ; comparison of constant volume and constant pressure scales for hydrogen between 0 °and - 190° C., by Dr. M. W. Travers and Mr. G. Sentor ; and the laws of electrolysis of alkali salt vapours, by Dr. H. A. Wilson. Mathematical papers are promised by Major P. A. MacMahon, F.R.S., Lieut.-Colonel A. Cunningham, Prof. A. G. Greenhill, F.R.S., Mr. C. V. Boys, F.R.S., and others. There will also be papers on astronomical subjects by Prof. H. H. Turner, F.R.S., Rev. A. L. Cortie, and Prof. D. P. Todd.

THE death-rates from accidents of various kinds in mines in the United Kingdom are dealt with in detail, both numerically and graphically, by Dr. Le Neve Foster, F.R.S., in his latest report, published as a Blue-book. The improvement which has been made may be judged from the fact that, whereas, in the early fifties, the underground death-rate was more than five per thousand, the average death-rate of the underground workers in 1900 was only 1·445. In 1851 about nineteen persons were killed per million tons of coal raised from mines, but last year the death toll on the same quantity of coal was reduced to four persons. Naked lights are still the principal cause of the accidents, more than seventy-five per cent. of the total number of deaths being ascribed to their use. In connection with the description of miscellaneous accidents we notice with interest the remark that during a severe thunderstorm in Staffordshire electricity passed down a shaft, and two men received a severe shock. Flashes of light were seen about pipes near the shaft. The following is a complete list of explosives which have passed the special test for use in mines, under conditions far more stringent than those of the ordinary list: ammonite, amvis, aphosite, cambrite, carbonite, electronite (second definition), kynite, Nobel Ardeer powder, Nobel carbonite, roburite (No. 3), saxonite, special bulldog, thunderite, and virite. As to electric safety lamps Dr. Le Neve Foster says the Sussmann Company have informed him that three or four thousand of their lamps are employed in collieries in the United Kingdom. It is of interest to notice that the total number of mechanical coal-cutters in use in the United Kingdom in 1900 was 311, of which 240 were driven by compressed air and 71 by electricity. The quantity of coal got out by these cutters was 3,321,012 tons. Gold mining is being successfully carried on in North Wales; 19,463 tons of quartz crushed at St. David's mine yielded on an average about 14dwts. of gold to the ton, and the net profits for the year amounted to nearly 40,000*l*.

THE Meteorological Office pilot chart of the North Atlantic and Mediterranean for the month of September shows that West Indian hurricanes have a tendency to keep further out on the ocean in this month than in July and August, the mean point of curvature being in about 28° N., 72° W., and individual cases have been known to curve in the same latitude as far as 52° W. Comparatively few of the centres enter the Caribbean Sea, and of those that do nearly all keep to the northern side. The origin of some of these storms is attributed to shallow disturbances moving westward in the vicinity of the Cape Verde Islands, associated with unsettled weather and strong winds. Hurricanes are rarely experienced on the north coast of South America, Curaçoa island being visited in September 1877, the only instance in seventy years. Local peculiarities in the winds on the African and American coasts are referred to, and there is a summary of the features of the winds of the Grecian Archipelago and also of the currents of the same region. An inset chart represents the third type of thunderstorm conditions over the British Isles, namely those which appear as secondaries to depressions in the north. The ice reports show that in July there was a diminution in the number of bergs seen on the Banks of Newfoundland, few being reported south of the latitude of St. John's. In the strait of Belle Isle and to a distance of about 200 miles north-eastward of Belle Isle itself, the steamer route was infested with great quantities of ice, heavy field ice and large bergs rendering navigation very difficult and tedious. One steamer was detained four days in the ice, another was obliged to retreat and make for the gulf of St. Lawrence by the south coast of Newfoundland. The most southern ice was in 41° N., 47° W., a very small piece, 20 feet by 40 feet, and only 4 feet out of the water.

SOME further particulars are given in *Symons's Meteorological Magazine* for August of the severe thunderstorm which occurred in London on July 25. It was in many respects similar to that which occurred on July 27 last year; both storms occurred after a period of great heat, and after an absolute drought of nearly three weeks. The barometric trace showed distinct disturbance at the two periods of greatest intensity, but there was an absence of the typical thunderstorm curve. The rainfall (2·85 inches in about four hours) has been exceeded on only one day in the forty-four years since the commencement of the Camden Town record, viz. in the great thunderstorm of June 23, 1878, when 3·28 inches of rain fell in an hour and a half. The greatest intensity of rainfall in the recent storm was ·23 inch in two minutes, being at the rate of 6·90 inches per hour. It is remarkable, considering the vividness of the lightning and its great frequency, that so little damage was done.

WE have received the Report of the Director of the Government Observatory, Bombay, for the year ending March 31, 1901. The labours of the observatory are directed in the first place to observations in magnetism, meteorology and seismology, and the discussion and publication of the results; and secondly to astronomical observations for the purposes of timekeeping and navigation. The Dines' pressure-tube anemometer gives very satisfactory results, and serves as a valuable check upon the Robinson velocity anemograph. The seismograph registered twenty-nine earthquakes during the year, besides 447 small and local movements. Among the various important duties performed at the observatory may be mentioned the rating of the chronometers of merchant ships which arrive at the port, and the transmission of weather and other reports to various newspapers and public bodies.

THE *Electrical Review* states that experiments are about to be made on the River Lea with the view to the adoption of a system of electric haulage of barges similar to that in use in France. A power station has been erected at Hertford, from which the current will be supplied by wires supported on poles to a trolley running on a narrow-gauge track along the towpath. It is anticipated that the barges will be towed at a speed of from three to four miles an hour at less cost than by horse traction. The system is to extend to Walthamstow, a distance of eighteen miles.

THE improvements in the locks and bridges, and the deepening of the waterway of the Aire and Calder Navigation, which have been carried out in recent years, have enabled for the first time in the history of the undertaking a sea-going steamer to navigate the canal from Goole to the middle of Yorkshire. The *Pioneer*, after a voyage of 500 miles from Fowey in Cornwall, delivered a cargo of 130 tons of china clay at Leeds. This vessel is $98\frac{1}{2}$ feet long, $17\frac{3}{4}$ feet beam and draws $7\frac{1}{2}$ feet of water. After the inception of the Manchester Ship Canal, several schemes were proposed for making a ship canal from the Humber to the centre of the manufacturing districts of Yorkshire. A proposal to establish a port at Wakefield was enthusiastically received at a meeting of representatives of the West Riding, the estimated cost of the scheme being six million pounds. The financial results of the Manchester Ship Canal have not given encouragement to the further prosecution of these schemes.

DURING the past few years a series of remarkable papers by Prof. Karl Pearson and his coadjutors has been published by the Royal Society in the *Philosophical Transactions* and *Proceedings*, on the foundations of a very comprehensive mathematical theory of evolution. Mr. R. Worthington (*Journal Anat. and Phys.* vol. xxxv. 1901, p. 455) gives some account of that portion of Prof. Pearson's work which bears an osteology as a branch of physical anthropology, in such a manner as shall be intelligible to non-mathematical readers. The application of mathematical analysis to the problems of evolution was introduced by Dr. Francis Galton and perfected by Prof. Karl Pearson, and the results already obtained are of such importance that biologists cannot afford to neglect them.

THAT portion of the brain where "impulses of diverse nature, coming from all regions of the body and from all the sense organs, may meet and play upon each other," that *sensorium commune* for which the ancient philosophers sought in vain for so many ages, is a region of the hemisphere which is surely worthy of a distinctive name. Such is the plea of Prof. G. Elliot Smith (*Journal Anat. and Phys.* vol. xxxv. 1901, p. 431), who suggests that it might be called the *pars crescens* (hemisphærii), in reference to the peculiar characteristic of its rapid expansion in the Mammalia; but instead of selecting a new phrase he prefers to use the term *neopallium*, as at every epoch in the history of the mammal this part of the brain shows a progressive increase in size, whereas the other superficial parts of the hemisphere become relatively or actually smaller and may even disappear almost entirely without any vital injury to the individual.

To the *Proceedings* of the Royal Physical Society of Edinburgh for 1899–1900, Dr. G. Wilson contributes a preliminary notice of the first appearance of the lung in the Australian lung-fish (*Ceratodus*), and a second on the embryonic kidney of the same. Dr. D. Hepburn notices certain mammalian remains (all referable to existing types) recently collected in a cave in Sutherlandshire.

IN the August number of *The Zoologist*, Mr. R. B. Lodge describes an interesting arrangement by means of which he obtained automatic photographs of the purple heron and spoonbill on the nest. A camera was fixed near the nest, provided with a string and catch so arranged that when the bird alighted it caused a "snap-shot" of itself to be taken. Curiously enough, before the photo of the purple heron was obtained, one of a marsh-harrier, which had come to rob the nest, was taken. With the aid of a flash-light the arrangement would be available for night use.

THE Imperial Department of Agriculture for the West Indies issues a continuation of its publications relating to the insects injurious to cultivators in these islands, in the form of a pamphlet on the "Scale Insects of the Lesser Antilles," of which a second instalment is to follow. The West Indian scale insect and allied members of the Coccidæ form, in spite of their minute size, some of the most troublesome pests against which the West Indian planter has to contend. According to the author, Mr. H. Maxwell-Lefroy, various poisonous or resinous washes, applied as spray, form the most efficient remedies; a list of those most suitable to each kind of crop is appended.

To the January issue of the *Proceedings* of the American Philosophical Society, Dr. R. W. Shufeldt contributes a further instalment of his series of dissertations on avian osteology, this contribution dealing with the skeleton of the cuckoos. Although not committing himself definitely to any opinion, and dwelling upon the imperfect state of our knowledge of the bony structure of this large group of birds, the author is inclined to confirm the view of the near relationship of the cuckoos to the plantain-eaters and bee-eaters. He believes, however, that several families of "picarian" birds "have a cuckoo-vein running all through them, strongly impressed in some cases, barely discernible in others. Indeed, these groups of birds seem to have arisen from some very ancient and common stock, but by the extinction of numerous related types . . . it has left in recent times the most puzzling collection that the systematist has to deal with."

THE second part of vol. vii. of the *Transactions* of the Norfolk and Norwich Naturalists' Society contains a number of papers, for the most part connected with the natural history of the county. Prof. A. Newton has a note on some bones of the crane from the Norfolk fens, and this is followed by an interesting account from the pen of Mr. T. Southwell of the breeding of that bird in the county. Documentary evidence is cited to prove that in 1543 cranes nested in Hickling Broad, and about the same time in the Cambridgeshire fens. Dr. S. F. Harmer describes and figures a dolphin taken in Cornwall, the flanks of which showed certain peculiar scratches. At first it was thought these might be due to the hooks of a cuttlefish, but subsequent investigation tended to show that they were made by other individuals of the same species, probably during the pairing season. The author is, however, of opinion that somewhat similar markings seen on other cetaceans may be due to the struggles of the cuttles on which they feed.

THE bulk of Part I of the Bergen Museum "Aarbog" for 1901 is occupied by a list of the Coleoptera and Lepidoptera of the Bergen district, drawn up by Mr. J. S. Schneider, and illustrated with a coloured plate. Of more general interest is an article by Dr. O. Nordgaard on the hydrography of the North Sea, largely based on the observations of two sealing captains. As the result of the investigations it appears that the effect of the Gulf Stream on the North Sea has been very variable during the last four years of the century. The favourable condition of the ice in 1897 and 1898 seems to have been owing to an influx of warmth characterising these years, while the unfavourable conditions noticed in 1899 and 1900 were due to a lack of the same influence. The years 1898 and 1899 severally represented indeed the maximum and minimum in this respect. This is confirmed by the fact that in the former year the development of the "plankton" was much above the average. Allusion is made to the influence of such temperature variations on the cod and herring fishery, as well as on sealing.

MR. W. W. DAVIS has a paper in "Studies from the Yale Psychological Laboratory" (vol. viii.), on some relationships between temperament and effects of exercise. His tests and observations are scarcely sufficient to establish very definite relations, but the conclusions at which he arrives are not without interest. The observations suggest that nervous persons, in training for the development of strength, require light practice, and phlegmatic persons require vigorous practice. The phlegmatic type of temperament is apparently characterised by the presence of much reserve energy of muscle and nerve cell. The nervous type has less reserve energy but a greater ability to use the energy at hand. It is not difficult to apply these principles to practical physical training. They make necessary on the part of the trainer a personal knowledge, secured either by means of observation or experiment, of the temperament of each man under his charge. The amount of work necessary in each case can then be apportioned with much greater exactness. Mr. Davis points out that it seems quite as certain that there may also be a direct application of these principles in the realm of pedagogy. The experiments show that, in the development of strength, mental factors are more necessary than muscular factors. If the principles can be applied to the development of will power and co-ordination, why not to memory, association, imagination, and reasoning as well? All have a physiological basis, and in so far all are governed, in a given individual, by the same principles of growth. There is at least a wide field here for inquiry and practical investigation. There can be no doubt that the present system of secondary and collegiate instruction, which requires an equal amount of work from all pupils, causes much harm to many individuals. Mr. Davis's results emphasise the importance of recognising the individual in the training of either physical or mental ability.

AN elementary text-book of zoology, which has been prepared for the Cambridge Natural Science Series by Mr. A. E. Shipley of Cambridge and Prof. MacBride of McGill University, Montreal, will be published on September 9 by the University Press in England and the Macmillan Co. in New York.

A CATALOGUE of works on chemistry and chemical technology in the library of the Patent Office has just been published as No. 6 of the Patent Office Library Series. The list comprises the titles of 885 works (79 serials, 806 text-books, &c.), representing about 3300 volumes. The titles are classified under 146 headings and sub-headings, so that students using the Patent Office library can readily find the works available upon any subject in chemistry.

THE United States Board on Geographic Names has issued a special report giving the accepted spellings of 4000 geographical words used in the Philippine Archipelago. When the islands were acquired by the United States in 1898, and new charts had to be prepared, much confusion existed as to the geographical orthography—Spanish, Malay, American and English methods of spelling native names being in use. Acting upon the advice of the Board, the U.S. Hydrographic Office adopted the spelling upon the best Spanish official charts and maps, and a list of about 4000 coastwise names was compiled, chiefly from Spanish sources. This is the list which has now been published. Another list, containing about 6000 Philippine geographical names, was prepared independently by Father Algue, director of the Jesuit Observatory at Manila, and these have been accepted by the U.S. Coast and Geodetic Survey for the atlas of the Philippine Islands shortly to be issued. To ensure uniformity, Father Algue has revised the present list, so that all the names in it now agree with those used in the Coast Survey atlas.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. H. S. Kemp; a Japanese Deer (*Cervus sika*) from Japan, presented by Sir Douglas Brooke, Bart.; a Short-headed Phalanger (*Petaurus breviceps*) from Australia, presented by Captain Gordon Wilson; two Common Kingfishers (*Alcedo ispida*), British, presented by Mr. W. Milne; two Rosy-faced Love-birds (*Agapornis roseicollis*) from South Africa, presented by Mrs. Harry Blades; an Alligator (*Alligator mississippiensis*) from Southern North America, presented by Mr. J. Foster Spence; a New Zealand Parrakeet (*Cyanorhamphus novae-zealandiae*), a One-wattled Cassowary (*Casuarius uniappendiculatus*), a Westermann's Cassowary (*Casuarius westermanni*) from New Guinea, two White-breasted Sea Eagles (*Haliastur leucosternus*) from Australia, an Angulated Tortoise (*Testudo angulata*) from South Africa, two Pale-headed Tree Boas (*Epicrates angulifer*) from Cuba, a Common Roe (*Capreolus caproea*), European, two Getulian Ground Squirrels (*Xerus getulus*) from Morocco, deposited; a Spot-wing (*Psaroglossa spiloptera*) from India, purchased; a Burrhel Wild Sheep (*Ovis burrhel*), an Axis Deer (*Cervus axis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER.

Sept. 1. 7h. 36m. Minimum of Algol (β Persei).
4. 16h. 2m. to 16h. 58m. Moon occults ϵ Tauri (mag. 3·7).
6. 10h. 48m. to 11h. 13m. Moon occults 71 Orionis (mag. 5·1).
7. Pallas in opposition to the sun.
9. 14h. 32m. to 15h. 25m. Moon occults κ Cancri (mag. 5·0).
12. Perihelion passage of Encke's comet.
15. Venus. Illuminated portion of disc = 0·795.
15. Mars. ,, ,, ,, = 0·933.
15. 15h. Venus in conjunction with the moon. Venus 1° 15′ N.
18. 12h. 30m. Minimum of Algol (β Persei).
21. 9h. 19m. ,, ,, ,,
27. 6h. 5m. to 9h. 13m. Transit of Jupiter's Satellite III.
28. 6h. 1m. to 6h. 41m. Moon occults 62 Piscium (mag. 6·0).

NEW ELEMENTS OF COMET 1901 (I.).—From observations made in May and June at the Cape and Cordoba (*Astronomische Nachrichten*, Bd. 156, No. 3734), Herr H. Thiele has computed a new set of elements for this comet, giving the following orbit:—

T = 1901 April 24·28845 Berlin M.T.

$$\left.\begin{aligned} \omega &= 203^\circ\ 2'\ 15''\cdot1 \\ \Omega &= 109\ 38\ 53\cdot1 \\ i &= 131\ 4\ 49\cdot3 \end{aligned}\right\} 1901\cdot0$$

$$\log q = 9\cdot388827$$

An ephemeris is also given founded on these revised elements, so that search for the now faint comet may be continued.

Ephemeris for 12h. Berlin Midnight.

BRIGHTNESS OF THE SOLAR CORONA, JANUARY 22, 1898.—In a paper read before the Royal Society, Prof. Turner gives a preliminary description of the results obtained from an investigation into the law of variation of the brightness of the solar corona in relation to the distance from the sun's limb (*Proc.* Roy. Soc., vol. lxviii. pp. 36–44). Instead of the rotating sectors used in previous similar investigations, a graduated gelatine wedge has been employed to diminish the intensity of the comparison beam. An entirely new method has been adopted for representing the results, which has led to the suggestion of a more satisfactory law for the variation of coronal brightness with the distance from the sun.

Up to the present time the relation usually adopted was that formulated by Prof. Harkness in 1878, viz.:—

$$\text{Brightness} \propto \frac{1}{(\text{distance from sun's limb})^2};$$

but this was not in agreement with the visual measures of Thorpe and Abney in 1886 and 1893.

The new relation now suggested is—

$$\text{Brightness} \propto \frac{1}{(\text{distance from sun's } \textit{centre})^6}.$$

Tables giving the measures along six different radii show sufficiently small residuals to warrant the formula being provisionally used to express the variation. It is found that a constant is required to be added to the formula, the physical interpretation of which is most probably the sky-glare present during totality, and which would necessarily give a certain amount of light all over the plate. The total brightness of the corona will thus depend on the area of sky included. Assuming this to be a circular area 5° in diameter, the total brightness of the 1898 corona would be about 2·4 times that of full moon, while the 1893 corona was only about 1·1 times brighter than the full moon.

THE SPECTROSCOPIC BINARY "MIZAR."—During March and April of the present year a series of excellent photographs of the spectrum of this star, ζ Ursæ Majoris, were obtained with Spectrograph IV. and the 33 cm. refractor at the Potsdam Observatory. Dr. H. C. Vogel has measured these, and gives the result of the reductions in the *Astrophysical Journal* (vol. xiii. pp. 324–328). On some of the plates as many as sixty-five lines are recognisable, including several of the strongest iron lines and lines of silicon and magnesium. When the period of maximum separation occurs, however, many of these become faint and the measures are more difficult.

On several of the plates the separated magnesium lines at λ 4481 appeared of unequal width, but no change in their behaviour was discernible after a coincidence.

The values of the relative motion are given for twenty-five plates obtained during the period 1901 March 24–May 1, ranging from 158 to 15 kilometres per second.

The motion of the whole system is given as 16 km. per second. A diagram is given showing the velocity curve most nearly representing the final reduced measures, and the period thus deduced is 20·6 days—considerably less than the period of 104 days deduced by Pickering about 1890.

The following provisional elements have been computed from the curve by Lehman-Filhes' method on the assumed values of

Period = 20·6 days.
Maximum relative velocity of A = 128 km.
,, ,, ,, B = 156 ,,

T_0 = 1901 March 28·60 (Rel. motion in line of sight = 0).
T = 1901 March 28·88.
ω = 101°·3.
e = 0·502.
$\log \mu$ = 9·4843.
μ = 17°·476.
$a \sin i$ = 35 million kilometres.

$$m + m_1 = \frac{4\odot}{\sin^3 i}.$$

NOVA PERSEI.—In the *Astrophysical Journal* (vol. xiii. pp. 336–7) Messrs. G. C. Comstock and J. Stebbins give a very exhaustive series of comparisons of the estimated brightness of Nova Persei from February 24 to May 12. The observations were made by the "grade" method of Argelander, the estimated error being 0·1 magnitude for a single comparison. The rapid variation of the star is well shown by the many cases where several observations were obtained during the same evening. The minimum magnitude recorded is 5·7. Most of the estimates were made with the help of an opera-glass, the comparison stars being those given on Hagen's special chart of the region.

THE FUTURE OF ELECTRIC TRACTION.[1]

IT is not so long since the Englishman, and perhaps more particularly the Londoner, first tasted the sweets of electric traction, but he has already found it so satisfactory, whether as a profitable investment or as a method of travelling at once comfortable, convenient and healthy, that he is clamouring for its rapid extension and development. It is beginning to be realised, too, that electricity as a motive power is not destined to be confined to metropolitan railways and suburban tramways. The electrification of our larger railways is now being discussed as a practical problem by the more far-sighted of our engineers, who have recognised that many of the railway systems characteristic of this country are peculiarly suited for electrical running. Mr. Langdon, now president of the Institution of Electrical Engineers, devoted a paper read last November before that society to the subject; and Major P. Cardew, in his recently delivered Cantor Lectures, again gave prominence to the question.

[1] "On the Supersession of the Steam by the Electric Locomotive." By W. Langdon. (*Journal* of the Institution of Electrical Engineers, vol. xxx. p. 124.)
"Electric Traction." By Major P. Cardew. Cantor Lectures. (*Journal* of the Society of Arts, July 12, 19 and 26.)

It is interesting to consider what are the conditions of working which would make a railway one in which the adoption of electric traction is likely to prove profitable, for unless the alteration results in the increased economy of the system it is clear that it is not likely to be made. "Electric traction," says Major Cardew, "tends towards the ideal of the continuously moving platform," and one may say that the more nearly a railway tends towards the same ideal the more likely is the adoption of electricity as its motive power. In those most closely approaching this limit, namely, the metropolitan railways, all other systems at present known have long been seen (by all except perhaps the directors of the London underground and district railways) to be doomed. The reason lies in the essential difference between steam and electric driving, namely, that in the one case the train must carry its own power generator whilst in the other the power is generated in bulk for a number of trains. Since the generation of power in bulk is much cheaper than in detail, the tendency with steam locomotives is to make each detail as large as possible, and therefore to run heavy trains at long intervals. With electric working, on the other hand, it is desirable to make the load on the generating station as constant as possible, which can only be done when the number of trains is large and each only takes a small fraction of the total load; for in such a case the stopping and starting of individual trains will only have a small percentage effect on the output of power. It will readily be seen, therefore, that for long-distance traffic the steam locomotive is likely for some time to come to hold its own, for here the number of passengers is not so great as to be able to support a very frequent service of light trains, and, moreover, the time taken over the journey, being nearly the whole of the day or night, practically fixes the starting times. With lines communicating between important towns not too far apart (about 100 miles is the limit given by Major Cardew), electric traction could be introduced with advantage; in this case a frequent service of light trains would be a great benefit, especially if a number of important centres lie on the route between the termini and if there is a field for metropolitan traffic at the ends of the line. In such lines our small but densely populated country abounds.

Many additional advantages are introduced at the same time as the principal gain in the lessening of the cost of power generation. Thus the driving power can be distributed throughout the train, which results in lessening the wear of the permanent way and also in a lessening of the slip of driving wheels, as a greater proportion of the weight of the train is used for adhesion. It is easier, too, to provide power for accelerating the train and for mounting gradients, as the extra power needed in these cases is derived from an outside source, whereas if a steam engine were made powerful enough for very quick acceleration it would be too powerful for economical working during the greater portion of its running time. The concentration of power generation at a few centres leads to many economies in working expenses; coal and water are only used at the generating station, and it is only there in consequence that means for their storage and handling have to be provided.

Those who are more keenly interested in this question will do well to read the paper by Mr. Langdon to which reference has been made above. They will there find the matter thrashed out in considerable detail, both in the paper itself and in the discussion upon it, with the estimated saving worked out from a consideration of the existing traffic over a section of the Midland Railway, fifty miles long, between London and Bedford. Major Cardew discusses the problem more generally, but in his third lecture enters with some detail into the equipment of an imaginary typical full-scale railway fifty miles long; for this he arranges a suitable time schedule and then estimates the amount of power required and the approximate cost of equipment.

Major Cardew equips his imaginary railway on the polyphase system, which he considers, on account of "the advantages obtained in regard to means of conversion and from the use of higher pressure," to be most suited for use on full-scale railways. Space does not permit us to enter into a discussion of the relative merits of three-phase and direct-current working, and we must content ourselves with referring the interested reader to Major Cardew's lectures, where he will find the question fully considered. Here, in England, we are not very familiar with polyphase currents, but on the Continent, and in Switzerland especially, there are many railways thus equipped, and there can be no question of the willingness of Continental engineers to introduce their wares into this country if, as is to be feared, we are incapable of supplying our own wants. Major Cardew, after considering and summing up the relative advantages of the two systems, gives his verdict against continuous current and feels "confident in prophesying the successful application of the polyphase system to the working of full-scale railways."

PRIZE-SUBJECTS IN APPLIED SCIENCE.

THE programme of subjects for which prizes will be awarded by the Société industrielle de Mulhouse next year has been issued, and copies can be obtained upon application to the secretary of the Society. In general chemistry, medals will be awarded for the best memoirs or works on the theory of the manufacture of alizarin reds; the synthesis of the colouring matters of cochineal; theoretical and practical study of the carmine of cochineal; study of the colouring matter of cotton; the composition of aniline blacks; physical and chemical modifications which occur when cotton fibre is transformed into oxycellulose; action of chlorine and its oxygen compounds upon wool; constitution of colouring matters employed in linen fabrics; synthesis of a natural colouring matter used in industries; and theory of the natural formation of an organic substance and preparation of the substance by synthesis.

In connection with dyeing, medals will be awarded for the best works presented on the following subjects:—A new mordant which admits of practical use; metallic solutions which give up their bases to textile fibres, and the conditions in which they are most effective; iron mordants and the part they play in dyeing according to their condition of oxidation and hydration; an aniline black which will not deteriorate in the presence of other colours or affect these colours, especially those of albumin; a soluble black for dyeing which will resist the action of light and soap as much as aniline black; a light blue cheap enough to be used to dye wools and not affected by boiling or by light; a blue similar to ultramarine which can be fixed upon cotton by a chemical process; a pure yellow which behaves like alizarin as regards its dyeing properties; a lake-red; a purple; a colouring matter to supersede logwood in its various applications; an assistant especially applicable to wool, capable of being cleared by simple washing, and composed of substances other than tin salts, hydrosulphites, sulphites, and bisulphites; new method of fixing aniline colours; a means of making colours resist the action of soap or of prolonged boiling; a means of producing the sheen of gold and silver upon materials by metallic powders; a manual containing tables showing the densities of as many inorganic and organic compounds as possible, in the crystallised state and in cold saturated solution; the synthesis of a substance having the essential properties of Senegal gum; a substance to supersede egg-white in the dyeing of linen; a colourless blood albumin which can be used instead of egg-white; a manual on the analysis of compounds employed in fabric printing and in dyeing; an indelible ink for marking cotton and similar materials; a practical method of removing grease spots from materials; a memoir on the use of resins in bleaching cotton fibre; a memoir on the bleaching and dyeing of various kinds of cotton; also memoirs dealing similarly with wool and silk; use of hydrogen peroxide for bleaching; improvements in the bleaching of wool and silk; and manuals on the bleaching of cotton, wool, silk, hemp and other fibres.

In connection with fabric printing, medals are offered for an alloy or other substance which has both the elasticity and durability of steel and also the property of not causing any chemical action in the presence of acid colours and colours containing certain metallic salts; a new cylinder machine capable of printing at least eight colours at once; and an application of electricity to bleaching, dyeing or fabric printing.

Among the prize subjects in mechanical arts are:—A means of recording by a graphical method the work done by steam engines in a given period (ordinary indicator diagrams do not fulfil the conditions); memoir on the spinning of combed wool; on the force required to start spinning machines; a motor for driving machines used in printing fabrics.

In electricity medals will be awarded for an electric motor the power and driving rate of which can be easily varied; a memoir on the comparative cost of electricity and gas for lighting a town having a population of at least 30,000; and comparative costs of electricity, gas, acetylene and water-gas for lighting an industrial establishment.

Money prizes as well as medals are awarded for some of the subjects, and all the competitions are open to every one, irrespective of nationality. The memoirs, designs or models submitted for the awards should be sent to the president of the Société industrielle de Mulhouse before February 15, 1902.

PROGRESS OF CIVIL ENGINEERING.[1]

IN response to a request of the Institution of Civil Engineers, Tredgold gave this ever memorable definition of civil engineering in 1828:—

"Civil engineering is the art of directing the great sources of power in Nature for the use and convenience of man; being that practical application of the most important principles of natural philosophy which has, in a considerable degree, realised the anticipations of Bacon, and changed the aspect and state of affairs in the whole world."

After a brief sketch of the objects of civil engineering, he added:—"The real extent to which it may be applied is limited only by the progress of science; its scope and utility will be increased with every discovery in philosophy, and its resources with every invention in mechanical or chemical art, since its bounds are unlimited, and equally so must be the researches of its professors."

A more concise and comprehensive definition of a great truth can hardly be conceived. From a physical and intellectual standpoint, a nobler aim for the exercise of the mental powers cannot be imagined than the direction of the great sources of power in Nature for the use and convenience of man. Psychology deals with mind alone, physics considers the nature and the laws of matter, but civil engineering treats of the intelligent direction of the laws governing matter so as to produce effects which will reduce to a minimum the time and physical labour required to supply all the demands of the body of man and leave more opportunity for the exercise of the mental and spiritual faculties. Philosophy, physics and civil engineering must work hand in hand. The philosopher must imagine, the physicist prove by experiment and mathematical computation, and the engineer apply to practice the laws of matter. Each must keep himself informed of the progress made by the others and must aid them by suggestions as to the lines on which research needs to be carried forward. The civil engineer, in attempting to solve some problem of construction, finds that he needs a material which shall possess a certain quality which he cannot discover that any natural product possesses. He calls the chemist to his aid, and he, from a study of the combinations of existing forms of matter which most nearly approach the desired ideal, reasons that some special combination of elements will entirely fulfil the conditions, and he experiments to find whether such combination can be made. Sometimes he is successful in his first attempt and sometimes not. But, whatever the result, he has added to his knowledge of the laws of combinations and has furnished to the philosopher fresh data for his generalisations and to the engineer a new material for his use.

As the knowledge of the nature of steel and the precise methods in which it can be manufactured have progressed, the engineer has gradually come to know just what he wants and how it can be produced, and, in his specifications, requires that the particular material of this class which he desires shall be of a certain chemical composition and also possess certain characteristics. The same is the case with almost every material which enters into the construction of engineering works of the present day. Matter in its original state is rarely used. Its chemical condition must be transformed before the engineer can utilise it with any confidence. That almost any desired transformation can be effected was not realised until late in last century. Starting with the atom, the ultimate particle of matter so far comprehended by us, the chemist found that several different kinds of atoms could be identified, and that these would combine in certain ways according to laws which could be formulated. But in the application of these laws and the tabulation of the results gaps were found to exist which could not be filled without the supposition that other elements existed than those already known. The existence of such elemental substances was confirmed by the revelations of the

[1] Abridged from an address delivered at the annual meeting of the American Society of Civil Engineers, June 25, by the president, Mr. J. J. R. Croes.

spectrum analysis, and, later on, several of such elements have been actually identified by the use of the electric current in creating vibrations in the ether. The limit is probably not reached yet, but as each new element is discovered its affinities are sought by the chemist, its sensibility to various forms of vibratory motion are investigated by the dynamist, as we may term the physicist who is seeking the laws of either heat or light or electricity, and then it is the function of the civil engineer to study how it can best be applied to the use and convenience of man. For, ever since the beginning of the nineteenth century, the evidence has been cumulative that matter in motion accounts for all physical phenomena, that motion produces energy, that energy is never wasted but is simply transformed, and that it manifests itself to the senses of man in various modes which are appreciable by the several organs of sense.

What our senses recognise as chemical affinity, heat, light and electricity are simply conditions of matter induced by vibrations or quivers or waves or strains, whatever we may call them, of different kinds and at different velocities. Neither matter nor motion can be originated by man, but, by a careful study of the sequence of events, control can be acquired of their modes of interaction, and natural phenomena can be artificially reproduced and other phenomena be produced. The intelligent application and direction of such means of control is the function of the civil engineer.

In considering the means of directing the great sources of power, the psychological element must not be forgotten. A mere intellectual application of the laws discovered by physical research is not enough to make a civil engineer. Breadth of view, the faculty of analysing what has been done so as to discover how and why some enterprises have been successful and others have not, and the ability to forecast the future, are essential. These qualities are largely natural, but may be cultivated to a great extent by study and experience. That there has been a wonderful advance in this direction during the nineteenth century is shown by the great number of civil engineers who hold positions of prominence in the management and control of large enterprises which require the exercise of faculties which cannot be acquired in any other way than by experience in the designing, construction and management of engineering works.

A prominent factor in causing this advance in engineering science which has occurred simultaneously on the Continent of Europe, in Great Britain and in America, has been the collaboration of men of science. Early in the century it became evident that the multiplication of lines of research demanded a differentiation of the labour of their prosecution and a close cooperation of the workers in any special line, and various associations of specialists were formed to promote various branches of scientific research. By the middle of the century it had become apparent that civil engineering was not the prosecution of a speciality, but was the coordination and direction of the work of all specialities in science and its applications.

Recognising, then, that progress is a law of Nature, the acceleration of progress is the aim of civil engineering. It strives to simulate the results of the slow processes of Nature by causing the sources of power to act rapidly in any desired direction. Appreciating, too, the fact that there is constant progress and that what now seems admirably adapted to our needs may in a short time require to be superseded by improved structures and processes, the tendency of the time is toward the production of works which will have a definite term of life, rather than towards the construction of everlasting monuments. We see that in the old nations, where the effort to build for eternity was made, time has outstripped the intent of the builders and what is antiquated is useless, and we see the same thing in our own streets to-day. The idea of building a monumental structure which will hand one's name down to future ages is a fascinating one, but it is simply a survival of the engineering of the Pharaohs.

The most thorough exemplar of the condition of civil engineering at the beginning of the twentieth century is the modern office building in a great city. One hundred years ago, the man of enterprise who resided fifty miles from a large city and wished to consult an engineer regarding a project for a new canal, arose before daylight, struck a spark from his flint and steel, which falling on a scrap of tinder was blown by him into flame and from that a tallow dip was lighted. In the same primitive manner, the wood fire was kindled on the kitchen hearth and his breakfast was cooked in a pot and kettle suspended from the iron crane in the fireplace. Entering the cumbrous stage coach, hung on leather springs, which passed his door, he was driven over muddy roads, crossing the narrow streams on wooden trestle bridges and the navigable rivers on a ferry boat, the paddle wheels of which were turned by a mule on a treadmill. At last he was landed in the city, where he walked through dirty streets paved with cobble stones until he reached his destination, a plain three-story brick building founded on sand, with a damp cellar and a cesspool in the back yard. Entering a dark hall he climbed a wooden staircase and was ushered into a neat room, rag-carpeted, warmed by a wood fire on the open hearth and lighted by a sperm oil lamp with one wick, for it was dark by this time.

To-day, his grandson, living at the old homestead, while comfortably eating his breakfast, which has been cooked over a gas range, reads in his morning paper that the high dam of the irrigation reservoir in Arizona, in which he is interested, sprang a leak the day before, and he telegraphs to his engineer in the city that he will meet him at his office at noon. Then, striking a match, he lights the lamp of his automobile, which is fed by petroleum brought 200 miles underground in pipes from the wells, rolls over macadamised roads to the railroad station, where he enters a luxuriously appointed train, by which he is carried above all highways, through tunnels, under rivers, or across them on long-span steel bridges, and in an hour is deposited in the heart of the city, where he has his choice of proceeding to his destination through clean and asphalt-paved streets in electric surface cars at nine miles an hour, elevated steam cars at twelve miles an hour, or through well-lighted and ventilated tunnels at fifteen miles an hour. Reaching the spot his grandfather had visited, he finds there a huge and highly decorated building, twenty or more stories high. Founded on the primeval rock, far below the surface of the natural ground, the superjacent strata of compressible material having been penetrated by caissons of sheet metal sunk by the use of air, compressed by powerful pumps driven by steam or electricity generated at a power station half a mile or more away, and these caissons filled with a manufactured rock such as the ordinary processes of Nature would require millions of years to produce, there is erected a cage of steel, the composition of which has been specified, and the form and mode of construction of which have been so computed that the force of the elements cannot overthrow the structure or even cause it to sway perceptibly. The meshes of this mighty cage are filled with products of the earth, the mine and the forest, transformed so as to be strong and light and incombustible, and all interwoven with pipes and wires, each in its proper place and noted on the plans. In one set of these pipes there is pure water, which has been collected from a mountain area of igneous geological formation, depopulated and free from swamps, on which a record of the daily rainfall is kept, and in which impounding reservoirs have been constructed by masonry dams across its valleys. From these reservoirs, the water, after filtration through clean sand, is conveyed thirty or forty miles through steel or masonry conduits to covered reservoirs, whence it is drawn as needed through cast-iron pipes to the building where it is to be used, and there distributed to all parts of it, chilled nearly to the freezing point through one system of pipes or heated nearly to the boiling point through another system. Another set of pipes carries steam which, passing through radiators, keeps the temperature of the air throughout the building at the proper standard for comfort. Sanitary conveniences are provided everywhere, and all wastes are consumed within the building by the surplus heat generated, leaving only ashes to be removed. Wires convey electric currents to all points, so that the occupant of a room, sitting at his desk, can by the touch of a button ventilate his apartment, illuminate it, call a messenger, be kept informed of every fluctuation in the markets, converse with anybody who is not "busy" within forty miles of where he sits and if entirely "up to date" can require his autograph and portrait to be reproduced before his eyes for identification. He dictates his correspondence and his memoranda, and "takes his pen in hand" only to sign his name. He need not leave his seat except to consult the photograph hanging on his wall, which shows to him the latest condition of the mine, the railroad, the arid lands irrigated, the swamps reclaimed, the bridge in progress, the steamship, the water-works, the tunnel or the railroad, the dam, the filter or the sewage works, the town, the machine, the power plant or the manufacturing establishment in which he is most interested.

Entering the brilliantly lighted hallway of this building, the air of which is kept in circulation by the plunging up and down of half a dozen elevators, the visitor is lifted at a speed of 500 feet a minute, past floor after floor, crowded with the offices of financiers, managers and promoters of traffic and of trade, lawyers, chemists, contractors, manufacturers, to the headquarters of the controlling genius of the whole organism, the civil engineer. For he it is to whom all the members of this microcosm must apply for aid and advice in the successful operation of their respective occupations. It is not his to mechanically transform elements into matter, or matter into other forms, or to show how energy may be produced, but to direct the application of energy to the various forms of matter, original or produced, in such way as to bring about the most satisfactory results in the most speedy and economical manner.

He has grown with the growth of the nineteenth century, and is, so far as the relations between man and matter are concerned, its most striking product. And so, while the definition given in the "American Edition of the Encyclopædia," which appeared at the beginning of the century, that "Civil engineers are a denomination which comprises an order or profession of persons highly respectable for their talents and scientific attainments and eminently useful under this appellation," is still true, it is hardly probable that the compiler of the Twentieth Century Encyclopædia will be content to let it stand without further explanation.

But the end is not yet: there are still many problems of Nature unsolved. The experience of every day shows that there are sources of power not yet fully developed, and we cannot but say with the great poet:

> "I doubt not through the ages one increasing purpose runs,
> And the thoughts of men are widened with the process of the suns."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A GOOD estimate of the character of the work of a College or University can be obtained from the investigations carried on by its staff and students. The following statement of research work done in the laboratories of the McGill College, Montreal, last session, published in the Annual Calendar of the College and University for the session 1901–1902, furnishes excellent evidence of sound instruction and scientific activity:—The effect of cold on the physical properties of iron and steel; the influence of bending on the torsional strength of metals; the properties of iron and steel as affected by annealing at moderate temperatures; experiments on frictional losses in 1½-inch pipes and bends under varying velocities of flow; experiments on the determination of the "Miner's Inch"; the separation and concentration of chromite, blende, nickeliferous pyrrhotite and certain other minerals by combined gravimetric and magnetic methods; the crushing and sizing of rocks by means of different types of apparatus; the treatment of Nova Scotia mispickel concentrates by cyanide, bromocyanide and chlorination methods; conditions affecting the wave form of alternators; and the effect of change of wave form in alternators on induction and synchronous motors: induction motors used as frequency changers.

THE Massachusetts Institute of Technology has lately introduced the degree of Doctor of Philosophy to supersede the former degree of Doctor of Science. The following statement of the requirements for the new degree is of interest as showing the tendency of technical education in the United States:—"The degree of Doctor of Philosophy certifies to high attainments of a grade which qualifies the recipient as a scientific investigator and teacher. The course of study leading to this degree is mainly one of experiment and research, accompanied by such other theoretical subjects as may be useful adjuncts to the main scheme of work. The candidate must pursue his studies and researches under the direction and oversight of the Faculty for at least two school years, furnishing from time to time such evidences of progress as the Faculty may require. His attendance must be continuous, except in cases of absence previously approved by the Faculty for the purpose of conducting researches and investigations in the field. He must present a thesis embracing the results of an extended original investigation, and must pass such final examinations as the Faculty may require."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 19.—M. Fouqué in the chair.—The chairman announced the death of two members of the Academy, Admiral de Jonquières and Baron de Nordenskiöld, and added a short account of their life-work.—The relations of psoriasis with neurasthenia: treatment by injections of orchitin, by M. F. Bouffé. Psoriasis is a trophonevrosis having its seat in the nervous centres and especially in the great sympathetic. It presents a great analogy with neurasthenia in its origin; in both diseases there is constantly a diminution in nervous activity, characterised by a fall in the urographic line of phosphoric acid. The treatment of both should consist in the invigoration without stimulation of the nervous system by injections of orchitin, the average dose being from 10 to 12 c.c. three times a week.—On a problem of d'Alembert, by M. F. Siacci.—On a particular critical point of the solution of the equations of elasticity, in the case where the forces on the boundaries are given, by MM. Eugène and François Cosserat.—On the general principles of mechanisms, by M. G. Kœnigs.—On the absolute value of the potential in isolated nets of conductors having a capacity, by M. Ch. Eug. Guye.—Researches on the mechanism of etherification in plants, by MM. E. Charabot and A. Hébert. Etherification in plants is produced by the direct action of the acid upon the alcohol, the action being favoured by a particular substance playing the part of a dehydrating agent, the latter being a diastase the dehydrating action of which is exercised in a chlorophyll medium.—Littoral deposits and movements of the soil during the secondary era in the Quercy and western Rouergue strata, by M. Armand Thevenin.—On the origins of the source of the Loue, by M. André Berthelot. Through the accident of a fire at an absinthe factory and the consequent liberation of a large quantity of absinthe, it became evident that the Loue represents a subterranean arm of the Doubs.—Observations of M. Berthelot on the preceding communication.—Influence of colour upon the production of the sexes, by M. C. Flammarion. A study of the effect of light of various colours upon the development of silk-worms.

PETROLEUM.

Handbook on Petroleum. By Captain J. H. Thomson and Boverton Redwood. Pp. xix+298. (London: Charles Griffin and Co., Ltd., 1901). Price 8s. 6d.

THE cooperation of Captain Thomson, H.M. Chief Inspector of Explosives, and Mr. Boverton Redwood, author of the encyclopædic "Treatise on Petroleum," in producing a handbook on the subject for the use, not only of officers of local authorities charged with the duties prescribed by the Petroleum Acts, but also of those engaged in the petroleum trade, strikes us as peculiarly happy.

The handbook commences with a short historical introduction, and the authors then proceed to a brief exposition of the theories of the origin of petroleum.

Whereas French and Russian chemists have supported the inorganic origin, a theory which in outline regards the oil as formed by the condensation under pressure of the gases generated by the action of water-vapour on metallic carbides, American geologists and German chemists favour the organic origin of petroleum.

Berthelot and Mendeleeff give the weight of their authority to the first theory, but there seems to be but little doubt that, though it is possible to produce petroleum in this manner, the organic origin is at once more probable and agrees better with the deductions of the geologist.

The supporters of the organic theory are also divided. The school of German theorists, among whom the names of Hofer and Engler stand out prominently, consider petroleum to be of purely animal origin, whereas many American geologists consider certain types, such as the oil of Pennsylvania, to be of vegetable origin.

At the meeting of German men of science and physicians at Munich in 1899, Krämer brought forward the view that petroleum is formed by the decomposition, under pressure, of the wax at the bottom of lakes and seas, which originated in the cells of diatoms; infusorial earth, which consists of the skeletons of Bacillariaceæ, exists in beds of enormous extent in districts where petroleum is found. In the discussion which followed, Engler, whilst admitting that some oil might be formed in this manner, upheld his view that petroleum is primarily derived from the submarine decomposition of fish, substantiating his theory by the announcement that he had found and analysed drops of petroleum from fossil bivalves in the Lias at Rothmatsch: we shall, however, be wisest to consider at present, with the authors of this book, petroleum to be of mixed animal and vegetable origin.

The next chapters are occupied by an account of the sources of supply, by a description of the methods for the production, refining and transport (the value of this section would have been considerably enhanced by diagrams and drawings), and by the enumeration of the names and chief properties of the commercial products of petroleum. Among much other useful information, the difference between "benzene," "benzine," "benzol" and "benzoline" is clearly explained. The next two chapters are devoted to "flash-point" and "fire-test."

The term "flash-point," as defined by the Act of 1879, has given rise to much misconception; it is not "the point at which petroleum gives off an inflammable vapour," but the temperature at which the oil gives off sufficient vapour to form an inflammable mixture with the air, a matter which, as the authors remark, depends entirely on the experimental conditions.

A considerable uniformity was obtained by the adoption (Act of 1879) of the Abel test, but the apparatus is capable of considerable improvement, and this improvement is met with in the Abel-Pensky test, a modification adopted by the German Government, the use of which the authors hope will shortly be legalised in this country. As the flash-point is lowered 1·6° F. for every reduction of an inch in barometric pressure, it is important to introduce a correction depending on the height of the barometer; such a table of corrections is given in this handbook and is used in Germany, but has not as yet received the sanction of Parliament. The Abel and Abel-Pensky tests are described with great detail and clearness, as is also the elegant method for ascertaining the presence of small quantities of petroleum vapour devised by one of the authors, namely by the use of the Redwood test-lamp, the principle of which depends on the halo or "flame-cap" which surrounds the hydrogen flame when burning in an atmosphere containing a small proportion of inflammable gas—the appearance of the flame under these conditions is illustrated by an excellent coloured photograph, and the diagrams throughout this section are most useful.

The rest of the book is occupied by an account of the legislation relating to petroleum and calcium carbide, including the precautions to be taken in the storage of the oil, and remarks on the construction of petroleum lamps. This section, which, like the rest of the book, is extremely clearly written, should be studied by all oil-dealers, lamp-manufacturers and local authorities; we venture to think its perusal would repay "the man in the street."

The law with regard to petroleum in force at the present time is contained in the Petroleum Acts of 1871, 1879, and 1881, but the history of petroleum legislation is one of "laborious attempt and discouraging failure." Subsequent to the Act of 1881, a Bill of fifty-seven clauses was introduced (in 1883) and referred to a Select Committee of the House of Lords; this was followed by a tour of inspection and the drafting, in 1884, of a second Bill, followed in its turn by an extension of the tour to America. In 1888 important conferences were held and memoranda presented to both Houses; the inevitable Bill was introduced in 1891 and a Select Committee appointed in 1894, which was reappointed in 1896 and 1897 and which reported in 1898. In 1899 Mr. Reckitt, a member of the committee, introduced a private Bill to raise the flash-point from 73° F. to 100° F. (Abel test). The Bill was defeated, but the "lobbying" on this occasion was such as to induce Mr. Healy to express wonder whether "all this was pure philanthropy."

The authors proceed to consider the reasons for this want of success. The present Acts are by no means unworkable, and have the merit of simplicity; but they simply control the keeping of petroleum spirit (oil flashing below 73° F.) and in no way interfere with the sale or storage of petroleum oil (oil flashing above 73° F.).

Though the Acts leave everything to the local authority, yet they are deficient in provision for local control; the excessive decentralisation which puts in the hands of district councils throughout the kingdom the administration of such technical legislation cannot but militate against the attainment of the object in view. But the legislative failure is not due to these minor points, but rather to the strong opposition to the raising of the flash-point and to the attempt to prohibit dangerous lamps by legal enactment.

The objections to raising the flash-point are, firstly, that it is uncertain whether this measure would have an appreciable effect in preventing lamp accidents, which are, as a general rule, not caused by explosions, but by over-heating of the gallery and wick-tube and by breaking the lamp, in which cases no oil flashing under 150° F. can be regarded as absolutely safe; and, secondly, that raising the flash-point would indubitably cause a rise in the price of the oil, when there would be tendency to supply petroleum spirit for lighting purposes, this spirit commanding, under present conditions, a higher price than petroleum oil. The administrative difficulty of the prohibition of dangerous lamps must be patent to everybody.

The yearly average of fatal accidents from lamps is 129, and this period represents the lighting, burning and extinguishing of a lamp at least 4,000,000,000 times; now during a similar period, 5500 deaths are caused by falling down stairs, yet no one would suggest that in consequence houses must be restricted to one story; lamp accidents are nearly always caused by lamps being dropped, knocked over or pulled off tables when lighted and occasionally a lighted lamp is used as a missile.

The authors give much sound advice as to the purchase of safe lamps and, in an appendix, add directions for the care and use of petroleum lamps, the circulation of which recommendations in leaflet form by local authorities would doubtless be attended by beneficial results. The concluding chapter is devoted to calcium carbide and acetylene.

The first appendix deals with the imports of petroleum, from which it appears that the import of Russian oil is increasing, whereas that of American is decreasing—the enormous increase in the importation of "petrol," motor-car spirit, is significant; in other appendices the Petroleum Acts of 1871, 1879, and 1881 are given, with comments and explanatory notes; memoranda and forms of license issued by the London County Council and a County Council report on the use of petroleum in manufactures and trades in London are also printed.

The book is well printed, clearly arranged, and possesses a good table of contents and an index; we must warmly congratulate its authors on having produced an altogether admirable handbook of the subject.

W. T. LAWRENCE.

COMMERCIAL EDUCATION.

Commercial Education at Home and Abroad: a Comprehensive Handbook, providing materials for a Scheme of Commercial Education for the United Kingdom, including Suggested Curricula for all Grades of Educational Institutions. By Frederick Hooper and James Graham. Pp. xiv + 267. (London: Macmillan and Co., Ltd., 1901.) Price 6*s.*

THE joint authors of this book are respectively the secretary of the Bradford Chamber of Commerce and the inspector for commercial subjects and modern languages to the West Riding County Council. They have done well to embody the results of their experience in a volume in which the promise held out in its somewhat lengthy title is creditably fulfilled. Very copious particulars are given in regard to the organisation and plans of commercial schools in the chief countries of Europe, notably France, Germany, Belgium and Switzerland. Designs of buildings, regulations and time-tables, both from these countries and from the United States of America, show in considerable detail how ample and varied is the provision made for the systematic teaching of "commercial" subjects, and how much our own countrymen have yet to learn in this department of national education. A considerable portion of the book is thus statistical and is made up of a great variety of official documents; but it is uncritical, and does not profess to do more than set forth existing facts, without discriminating very exactly between those portions of an elaborate programme which are of merely occasional and local importance and those which are entitled to rank as essential in every complete scheme of commercial and economic training.

In dealing with the conditions under which our own tentative efforts after such training have hitherto been made, the authors write with the authority which comes from intimate knowledge, and their suggestions are of much practical value. They rightly insist on the need of a good foundation of general knowledge before any attempt is made to differentiate the course of a boy's instruction in the direction of any trade or profession. But they urge that when the time for such differentiation arrives, there should be as much encouragement offered by public authorities to the training of skilled merchants. as to the education of the skilled manufacturer or artisan. The policy of the Education Office, and the award of special grants and recognition for "Science and Art," have helped to encourage a general belief that all efforts to prolong the education of a youth beyond the ordinary school age and to fit him for the practical business of life should take a scientific direction, the domain of "science" being understood to include chemistry, physics and other studies bearing on material industries and production. "At present," the authors say, "provision is made whereby the science student may specialise in the direction of mechanical and electrical engineering, chemical industries and textile trades. But for the commercial student no such opportunity exists."

The contention that this is too restricted a view of the aims and scope of a technical or continuation school is, in our opinion, well grounded, and ought to lead to a fuller official recognition of the need for variety in Polytechnics and other institutions which do not come necessarily under the designation of "science and art" schools.

The problem how to determine the curriculum of a special school for youths of fifteen or sixteen destined for the conduct of business in a merchant's or banker's office becomes, therefore, one of considerable practical importance, and a large part of this book is devoted to its solution. Prominent among the conditions of success is the practice of *oral* instruction in modern languages, and constant conversational exercise as a necessary preliminary to book work and the technicalities of grammar. "The ear often remains untaught even after the eye has grasped all there is to know of the grammar and construction of the language." In this connection the particulars given in the book respecting the travelling scholarships of Germany and Switzerland and Belgium, and other devices for acquiring practical familiarity with the spoken language, are helpful and suggestive. The authors very properly insist on the need of a thorough acquaintance with arithmetic; but they evidently attach more importance to varied practical exercise in the art of computing, and to its application to tariffs, freightage, exchanges and other technicalities which have a visible and immediate relation to markets and counting houses, than to arithmetic as a science. The best experience on this subject, however, points to the conclusion that the learner whose attention has been directed, by means of demonstrative lessons and by some instruction in algebra, to the theory which underlies the truths of arithmetic, is in a better position to apply his knowledge in after life to business problems, whatever form they may happen to take, than he who has prematurely loaded his memory with rules and terminology relating to the details of commerce. On the subject of geography, and the effect of climate and physical conditions upon the nature and value of products, some hints are given which are well calculated to suggest to teachers more practical and interesting methods of teaching than are generally adopted in geographical lessons. The authors are right also in attaching importance to some knowledge of political economy, a subject which receives a good deal of attention in the higher commercial departments attached to the *Realschulen* of Germany. It is hardly recognised in England yet that the elements of social economics and the general conditions of industrial prosperity, the relative values of different kinds of labour, the laws which govern the rate of wages and the interest of money are subjects which can be made very intelligible and attractive to young people towards the end of their school life, and before entering into the arena of business competition. Such knowledge is not without a moral value of its own, for it reveals to the learner the need of industry, forethought, punctuality, self-restraint and thrift, and goes far to show the relation of conduct to real success in life.

The particulars given in this book respecting the College of Commerce and Politics in the University of Chicago, the Higher Institute of Commerce at Antwerp, the School of Commerce in Neuchâtel, and the commercial courses of University grade at Magdeburg Frankfort, Berlin, Dusseldorf and Leipsic, may serve to remind us of the fact that in England scientific preparation for the profession of commerce has hitherto not been recognised as a legitimate part of University work. A step has indeed been recently taken, thanks to the boundless munificence of Mr. Passmore Edwards, towards the permanent establishment of a School of Economics and of Commerce in connection with the renovated University of London. Much may be hoped from this novel and interesting experiment. *Inter alia* it may have a great effect on schools and other institutions of a lower rank, whose pupils will hereafter graduate in the new Faculty of Commerce. It is one of the offices of a University to show how the higher professions may be aided and quickened, and by setting up a lofty standard of thorough and scientific preparation, to reveal the true relations of academic culture to the qualities which make successful merchants and captains of industry. If this object be attained at the apex of our educational structure in the Universities, the aims of those who control the lower agencies, such as commercial classes in Polytechnics and in secondary schools will become clearer, and the practice of those institutions will be freed from the narrowing influences which have been long associated with the more ignoble type of "commercial academy."

The modest design described in the preface and the title of this volume has, on the whole, been usefully and sensibly attained. Those readers who seek the latest information respecting the ideals of "commercial education" which prevail in America and on the European continent, and the machinery which exists for translating those ideals into practice, will find much to interest them. But those who are trying to make up their minds on the larger problems—What is the place which special knowledge of commercial subjects ought to hold in a scheme of liberal education? How are we to secure that the higher claims of manhood and intelligence shall not be sacrificed prematurely to the lower claims of money-making and "getting on"? and What other studies ought to be pursued concurrently with business training in order to maintain the right balance of character in the future citizen?—must look elsewhere for the help and guidance they desire.

THE BIRDS OF ICELAND.

Manual of the Birds of Iceland. By Henry H. Slater, M.A., F.Z.S. Pp. xxiii + 150; 3 plates and map. (Edinburgh: David Douglas, 1901.) Price 5*s*. net.

MR. Slater has very acceptably filled the want, which many of us have felt, of a handy manual on the birds of Iceland. Much information on the subject is to be found scattered among Icelandic, Danish, German, Latin and English books and periodicals (the bibliography in the present volume comprises more than sixty titles), and this has now been revised and condensed in a compendious, handy form. Added to this we have now the personal observations made by the author in the occasional visits he has paid to Iceland during the last fifteen years, making altogether the most (indeed the only) complete account of the birds of this out-of-the-way corner of Europe which we possess. Without ministering to the insatiable appetite of the egg collector by disclosing the exact breeding localities of the rarer birds, the author has striven to make his manual useful to the many Englishmen who go to Iceland every year for various purposes, and who may take some interest in its birds. Besides reviewing and recommending certain earlier accounts of the ornithology, he names a good guide-book and some maps; and he gives a brief but useful description of the plumage of most of the birds (except those that are common and universally known) and also of the nests and eggs. In the introduction, too, we find some very necessary remarks on the English habit of misspelling and mispronouncing Icelandic words. And following this, and a statement upon the law as to the close-time for birds in Iceland, are three pages of most instructive suggestions on the right pronunciation of the language. All the species on the Icelandic list (one hundred and three, exclusive of eleven the occurrence of which is doubtful, and one, the great auk, which is extinct) are clearly and accurately dealt with in the body of the work; and the native names of the birds, if any, are indicated. The volume is in truth a manual, and its handy size will enable any traveller, however light his baggage, to find room for it.

From its geographical position, far north, and on the extreme west of the Palæarctic region, the avifauna is, as might be expected, a somewhat poor and limited one. It is made up, roughly speaking, of thirty-seven resident species, twenty-seven summer migrants (making sixty-four breeding species, three of which are a little doubtful), twenty-one occasional visitors and eighteen rare stragglers. The resident land-birds number only seven, and the land-birds which come to Iceland in summer to breed only five. The fauna is poorest in Passeres, of which we in England have so many; in Iceland there are only nineteen, eleven of which are only occasional or rare visitors. There are seven birds of prey on the list, two of which are resident and one a summer migrant. The three owls are only visitors. There is one game-bird, viz. the rock ptarmigan. We should add that the author is not responsible for this attempt to analyse the Icelandic avifauna. The great auk at one time resorted to Iceland. Nowadays, perhaps, the northern wren, the great northern diver (a western species, breeding nowhere else in Europe, unless it does so in the north of Scotland), and the Iceland falcon, famous among falconers in old days, are the most interesting birds to be found there. With regard to the wren (which is protected all the year round by law) the author remarks that there can be no reasonable doubt that the great increase of domestic cats in Iceland of recent years is leading very rapidly to its extermination—a fact which bird-protectionists in England would do well to lay to heart. But Iceland is very rich in ducks and geese, sixteen—possibly eighteen—species breeding there. Perhaps from a zoo-geographical point of view Iceland is most interesting as forming a link between the Palæarctic and Nearctic regions. Indeed, the number of birds which are common to the Icelandic and Greenlandic avifaunas, either as regular inhabitants or wanderers, is surprising. The manual, illustrated by three interesting plates and a map, is one of the most acceptable books which have fallen into the hands of the ornithologist for a long time.

OUR BOOK SHELF.

Blütengeheimnisse: Eine Blütenbiologie in Einzelbildern. By Georg Worgitzky. Mit 25 Abbildungen im Text. Buchschmuck von J. V. Cissarz. Pp. x + 134. (Leipzig: Teubner, 1901). Price 3 marks.

THIS title recalls that which was used in 1793 by Christian Konrad Sprengel, and to him the author traces the beginning of the bionomical study of flowers and their fertilisation which forms the subject of the little book before us. Since Sprengel laid the foundations there have been many workers, notably Darwin and Hermann Müller, and many new facts have come to light, while others observed more than a century ago have been rendered more precise. Therefore the author has been led to supply an introduction to the study, simple enough for beginners, and at the same time up-to-date. His method has been to select two dozen common plants, in flower at various times of year from February to October, and to tell the story of their pollination.

Poppy, wild rose, lime, buttercup, forget-me-not, meadow cranesbill and wild radish form the first and simplest group; white dead-nettle, iris, violet, campanula, figwort, cowslip and pink introduce the student to slight complications; broom, spotted orchis, wild carrot, centaury and ling illustrate special adaptations; while flowers pollinated by the wind are exemplified by ribwort, rye, hazel, willow and pine tree. The second part of the book is occupied with a simple discussion of the parts of the flower, the modes of attracting useful visitors, and warding off those that are injurious, dichogamy, self-pollination and kindred topics.

We cannot say that there is either novelty or individuality in Worgitzky's book, but it is clear, accurate, without waste of words, and objective from first to last. The pages are adorned with decorative devices and there are twenty-five simple figures with the amount of enlargement always indicated. Our only grumble is that the author keeps so consistently to the *rôle* of the descriptive naturalist and does not discuss the numerous evolutionist problems which his facts inevitably raise in the inquiring mind. Of course this must have been done deliberately, but we think that the author should have given clearer indication that beyond the floral secrets which he lays bare there lie others not less fascinating, though more mysterious.

The Lepidoptera of the British Islands: a Descriptive Account of the Families, Genera and Species Indigenous to Great Britain and Ireland, their Preparatory States, Habits and Localities. By Charles G. Barrett, F.E.S. Vol. vii. Heterocera, Geometrina. Pp. 335. (London: Lovell Reeve and Co., Ltd., 1901.) Price 12*s*. net; large paper, with coloured plates, 63*s*. net.

AMONG the numerous smaller publications on British Lepidoptera, most of which are useful and interesting in their own way, Mr. Barrett's great work pursues the even tenor of its course, a Triton among minnows, and likely to hold its place as the standard work for the student of British Lepidoptera for many a long day.

The present volume includes the full life-history, as far as is known, of eighty-four species of Geometridæ considered as British, two or three more being incidentally mentioned as European species probably admitted into our British lists by error. These are placed in the three families Boarmidæ, Geometridæ and Acidalidæ, the genus Ephyra being included in the latter family (Ephyra and Hyria being the only genera of the last family included in this volume), while the portion of the Boarmidæ which falls into it includes species formerly classed in Guenée's families Fidonidæ, Ennomidæ, Amphidasidæ, Boarmidæ, Hibernidæ, Zerenidæ and Ligidæ. Guenée's subdivision of the Geometridæ was never accepted in Germany, where the number of families was reduced by many authors to two; and in 1895 Sir George F. Hampson, in vol. iii. of his "Moths of British India," cut down Guenée's numerous families to six, in which he has been followed by many writers since, including Staudinger and Rebel in the catalogue just published. We believe ourselves that, though Guenée may have established more subdivisions than necessary, yet that the modern reaction has gone too far, and that some of his families which have been now abandoned will subsequently be reinstated.

Of the general execution of Mr. Barrett's work we have spoken fully in our notices of previous volumes. The present volume contains detailed notices of several species of considerable interest, such as *Nyssia zonaria*, *Abraxas grossulariata* and *Hibernia defoliata*. Mr. Barrett does not seem to be aware that *Nyssia zonaria*, an insect of our dry coast sand-hills, is said to be found in marshy localities instead, in France. W. F. K.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Testing of some Ballistic Experiments.

WHEN the Council of Military Education directed my attention to the science of ballistics in 1864, I came to the conclusion that a thoroughly good chronograph would solve all practical difficulties. The newly-invented instrument was first tried in 1865 with ten screens 120 feet apart, by the use of a 12-pr. Armstrong B.L. gun, when eleven satisfactory rounds were obtained. (Report (84/B/1941), and (*Proc.* of the R.A. Inst., 1866.) Afterwards Government decided to have systematic experiments made to determine the resistance of the air to ogival headed projectiles ($1{\cdot}5d$) fired from 3, 5, 7 and 9-inch M.L. guns, which were carried out in 1867–68 for velocities 900 to 1700 f.s. The results then obtained are still in use.

In 1871–72 I published general tables, S_v connecting range and velocity, and T_v connecting time and velocity. These tables were adapted to calculate the motion of a projectile when moving in the direction of its axis and acted upon only by the resistance of the air. These tables have now come into general use.

In order to test my first trial experiment of 1865, I will now calculate, by the use of these general tables, S_v and T_v, founded on the results of experiments 1867–68, the time in which the experimental projectile would travel from the first to each succeeding screen, for comparison with the average times determined by the trial experiments, and published 1865–66. Here $w=11{\cdot}5625$ lbs.; $d=3$ inches; $d^2/w=0{\cdot}77838$; $w/d^2=1{\cdot}28472$; $S_v = S_V - sd^2/w = 41261{\cdot}883 - n93{\cdot}406$, where n is to be taken 0, 1, 2 . . . 9 in succession to obtain the velocity at each screen. And $(T_V - T_v)w/d^2$ gives the time in which the velocity of the projectile falls from V to v. (Tables in "Text-book of Gunnery, 1897.")

(α)

Screen.	Exp. time 1866.	Calc. time 1901.	Difference.
	"	"	"
1	0·00000	0·00000	0·00000
2	·10489	·10503	– ·00014
3	·21106	·21121	– ·00015
4	·31845	·31861	– ·00016
5	·42705	·42743	– ·00038
6	·53684	·53714	– ·00030
7	·64780	·64814	– ·00034
8	·75988	·76030	– ·00042
9	·87309	·87361	– ·00052
10	·98831	·98756	+ ·00075

Further, the mean velocity of the projectile, at every 10 feet from the first screen, was calculated from the results of the first trial experiment, and published in the *Proceedings*, 1866. I will now *calculate* the velocity of the projectile at every 100 feet for comparison. Here $S_v = S_V - sd^2/w = 41254{\cdot}1 - n77{\cdot}7838$, where n must be taken in succession 0, 1, 2, &c., to find the velocity at 130, 140, 150, &c., feet from the gun. The following results have been thus obtained:—

(β)

Dist. from gun.	Proceedings, &c. 1866.	Calculated 1901.	Difference.
Feet.	f.s.	f.s.	f.s.
130	1149·4	1149·0	+0·4
140	1148·2	1147·9	+0·3
150	1147·1	1146·7	+0·4
200	1141·3	1141·2	+0·1
300	1130·2	1130·2	0·0
400	1119·4	1119·4	0·0
500	1108·8	1108·9	–0·1
600	1098·7	1098·8	–0·1
700	1089·0	1088·9	+0·1
800	1079·6	1079·5	+0·1
900	1070·5	1070·5	0·0
1000	1061·7	1061·9	–0·2

These two examples (α) and (β), comparing the results of experiment published in 1865–66, and of calculation in 1901, conclusively show the remarkable accuracy

(1) of the trial experiment of 1865,

(2) of the systematic experiments 1867–68,

and (3) of the general tables, 1871, used to connect (1) and (2).

This chronograph was used in all subsequent experiments.

The experiments of 1867–68 were continued by the use of a new 6-inch B.L. Armstrong gun in 1878–79 (Report 84/B/2853), and further with a new 8-inch Armstrong gun in 1880 (Report 84/B/2909). The coefficients of resistance to ogival headed shot ($1{\cdot}5d$) for velocities 100 to 2800 f.s. were thus determined. At an early period it was decided to employ J. Bernoulli's method of calculating trajectories. As opportunity offered, the calculation of auxiliary tables (X), (Y), (T) and (V) was proceeded with, of which 97 pages were published in 1873, and 48 pages in 1881, for the cubic law of resistance. And 70 pages were published in 1890 for the Newtonian law. The ogival form of head ($1{\cdot}5d$) chosen by Government was a very good form for standard experiments, as such projectiles were steadier than more acutely pointed projectiles, and the results obtained were easily adapted to other useful forms by using $\kappa d^2/w$ instead of d^2/w. Thus ogivals ($2d$) were found to encounter a resistance 3 per cent. less than the ogivals ($1{\cdot}5d$), which gives $\kappa=0{\cdot}97$, and I do not remember having had to use any smaller value of κ. I consider that a reduction of 5 per cent., or $\kappa=0{\cdot}95$, would be the least value of κ for projectiles of any practical use.

The only difficulty in experimenting was when the velocity was *low*, for then the trajectories were much curved. But the results obtained were tested by the calculation of 32 rounds of English 6·3-inch Howitzer, and 82 rounds of German 15 cm. Kurze Kanone for velocities 330 to 750 f.s. and found satisfactory. (Final Report, pp. 45–47.) The results for *high* velocities were tested by calculating, by the use of the general tables ($\kappa=1$) the times over given ranges of 1000, 2000, &c., yards, where the elevation of the gun was low, using horizontal muzzle velocities for the 4-inch B.L. 1884; the 6-inch Q.F. 1891; and 1893; the 9·2-inch B.L. 1898; and the 12-inch B.L. gun; for velocities 1000 to 2600 f.s. My coefficients of resistance appeared to be slightly too low. (Second Supplement, p. 15.)

When trajectories are calculated as tests of coefficients, it is necessary that both the calculated range and time of flight agree with experiment. But when an elongated shot was fired with a high velocity, it was found that both the calculated ranges and times of flight were shorter than those given by experiment. If then the resistance was reduced so as to give the desired range, the calculated time of flight was found to be too short. Hence it was clear that the error could not be corrected by any change of coefficient of resistance.

When elongated shot came into use, it was well understood that the projectile would be deflected upwards by the resistance of the air, so as to increase the elevation for which the gun was laid. This was named "kite-like action" in England, and Didion remarked that there would be a considerable deviation of the projectile "tant dans le *plan vertical*, que dans le plan horizontal" (*Traité*, xiii. 1860). Suppose now that the range r and the time of flight t, for an elevation α, have been carefully calculated. Then from the range table of the same gun, corresponding to same range r, find t' the time of flight, and α' the elevation. Then if $t=t'$ the coefficients of resistance giving the required time and range, are correct, and $\alpha-\alpha'$ is due to kite-like action. Thus, using the range table of the 4-inch B.L. gun: $v=1900$ f.s.; $w=25$ lbs.; $\alpha=12°$; and $\kappa=0·97$.

(γ)

	Range.	Time of flight.	Elevation.
Calculation ...	$r=5666$ yards	$t=17''·008$	$\alpha=12°\ 0'$
R. Table ..	$r=5666$,,	$t'=16''·964$	$\alpha'=11°\ 26'$
Difference ...	0	$t-t'=0''·044$	$\alpha-\alpha'=0°\ 34'$

Here for a range of over three miles, the calculated and observed times of flight, from point to point, differ by only $0''·044$, a negligible quantity. The resistance of the air must therefore have increased the elevation, for which the gun was laid, by $\alpha-\alpha'=34'$, due to jump and kite-like action, for an elevation of the gun of 11° 26'. The whole range table of the 4-inch B.L. gun was thus treated in 1892 (NATURE, No. 1190). These calculations have recently been repeated for elevations 7° to 20°, and published in my Second Supplement, where all the leading steps in the calculation of the ranges, &c., have been given. It was then found that when an elevation of 7° is given to the gun, 21' is added to the elevation by kite-like action, so that 7° + 21' must be used for the elevation when it is required to *calculate* the range and time of flight for an elevation 7° of the gun. The elevation of the gun is given in degrees below, and the addition thereto made by kite-like action and jump is given in minutes, 7° + 21', 8° + 23', 9° + 26', 10° + 29', 11° + 33', 12° + 38', 13° + 45', 14° + 53', 15° + 63', 16° + 74', 17° + 86', 18° + 98'.

From the results of calculations of range and time above referred to, I have deduced the following table :—

Range.	Time of Flight.			Elevation.		
Yards.	R.T.	Calculated.	Diff.	R.T.	Calculated.	Diff.
	"	"	"	° '	° '	'
4000	10·49	10·35	−0·14	6 21	6 32	+11
5000	14·30	14·19	−0·11	90 12	9 37	+25
6000	18 40	18·51	+0·11	12 36	13 18	+42
7000	23·50	23·59	+0·09	16 32	17 59	+87

showing clearly that both *range* and *time* of flight—given by *experiment* and *calculation*—agree, when a proper allowance is made for jump and kite-like action.

From the fair application of all these tests, it appears that calculated and experimental ranges and times of flight agree perfectly well for all practical purposes. Hence the laws of resistance determined by me—the general tables published by me—and the adaptation by me of J. Bernoulli's method of calculating trajectories are all quite satisfactory. But care will be required not to make my methods responsible, in any way, for the disturbing effects of jump or of kite-like action. Consequently range tables cannot at present be prepared by calculation alone, but when obtained by experiment, they may be tested at any point by the method (γ) already explained.

This chronograph might be used with great advantage to test the shooting qualities of all big guns. For this purpose the elongated projectiles should be provided with heads of similar forms. The charges used should be such as would give the velocity v, for which the gun is to be tested, near the middle screen. Fire each projectile through the equidistant screens till n satisfactory rounds have been obtained. Calculate K_v', K_v'', &c., for each of these rounds. Then the approximate value of $K_v=\frac{1}{n}(K_v'+K_v''+\&c.)$, and the mean error will be an indication of the steadiness imparted by the gun to its projectile, and so on for any number of guns. The shooting qualities of any guns could be compared for the velocity v, by simply comparing the numerical values of K_v given by each gun—the lower the numerical value of K_v the better the shooting. Target practice might be carried on simultaneously with these screen experiments. The best of the guns taken in South Africa should be brought home and tested in the manner above recommended.

August 1901. F. BASHFORTH.

Horn-feeding Larvæ.

So far back as June, 1898, you published in NATURE a short article from my pen dealing with "Horn-feeding Larvæ"; it opened up the question as to whether the larvæ of the insect *Tinea vastella*, Zell. = *gigantella*, Stn. = *lucidella*, WKr., fed on the horns of living animals. I mentioned at the time that Dr. Fitzgibbon, in 1856, brought home from the Gambia two pairs of horns, one belonging to *Kolus ellipsiprymnus* and the other to *Oreas canna*, which he had purchased from the natives; the horns were perforated by grubs enclosed in cases which projected abundantly from the surface of the horns, the blood at the base of the horns not having thoroughly dried up on them when brought to market.

Dr. Henry Strachan, of Lagos, wrote a letter, dated July 22, 1898, which appeared in NATURE, and in that letter he stated that the living horns were attacked and infested with the larvæ, as cocoons and pupæ had been extracted from such horns within an hour of the killing of the animals owning them. This he states on the unimpeachable authority of an officer who made the observation.

During 1899, 1900, and until July of this year, I have travelled very considerably in West Africa, having spent these years in Northern and Southern Nigeria, as well as Ashanti and the hinterland of the Gold Coast; I have made close observation of many species of horned animals, and have spent many days with native big game hunters. I have seen many cases in which the horns of dead animals have been infested with the larvæ of the *Tineidae*, but have never met with it in those of living animals. The natives with whom I have been associated, who are keen hunters and extremely keen observers, assure me they have never seen any protuberances containing grubs on the horns of living animals. During our campaign in Ashanti, I questioned officers who came with troops from all parts of the West Coast as well as the East Coast of Africa; also some from Uganda and the Lakes: they all unhesitatingly say that they have never seen cocoons on living animals, although well acquainted with them on the horns of dead animals. Dr. Fitzgibbon's statement stood alone until Dr. Strachan's letter appeared. I venture to suggest that the point still remains *sub judice*. W. J. HUME MCCORQUODALE.

August 30.

NEW GARDEN PLANTS: A STUDY IN EVOLUTION.

THE appellation "new garden-plants" is rather puzzling to those who are neither botanists nor gardeners, and, indeed, it is used with somewhat different significations by both these classes of experts. Considering that not the least of the many services rendered by the Royal Gardens, Kew, is the annual publication, as an appendix to the *Kew Bulletin*, of a list of "new garden plants," some explanation of what is meant by this designation may not be without interest. Let us take an illustration. The maidenhair tree, *Ginkgo biloba*, was in reality introduced into our gardens in 1750 or thereabouts. But let us suppose for our present purpose that it was introduced only in this year of grace 1901. Would it in that case have any right to be considered a "new plant"? If we look on it as the direct lineal descendant of a tree that grew in Greenland in Miocene times and had its ancestry still further back in the Oolitic period, we could hardly consider it as "new." The only novelty about it would be its introduction into gardens. Similarly, the Welwitschia, now in cultivation at Kew and elsewhere, was, in garden parlance, a new plant. It was new to Welwitsch when he discovered it in the deserts of Mossamedes in South-West Africa, but nobody looking at the uncouth "monster" would deem it new. Rather would he think of it, as he has a clear right to do in the case of the Ginkgo, as a survival from a prehistoric past. Welwitschia has not, so far as we know, been discovered in a fossil state, but if our Antarctic "discoverers" should light upon its traces near the South Pole, no one would be greatly surprised.

In such cases as these, then, it is the introduction into gardens as cultivated plants that constitutes the novelty. And so it is with the hosts of species of orchids, palms, ferns and other plants with which the zeal of botanists or the enterprise of collectors enriches our gardens. Many of these are absolutely new—new to science, that is, as well as new in gardens. Others are novelties so far as the garden is concerned, but have previously been known to, and duly recorded by, the botanist.

But there is still another category of "new garden plants," and one of such vast interest to the student of evolution that we cannot but express our astonishment that so fertile a field of research has hitherto attracted so few labourers. We allude to new plants actually created in gardens by the skill of the gardener. The materials, no doubt, exist in nature, the gardener does but rearrange them, as the milliner forms "ravishing creations" by tasteful intermixture of tulle and ribbon. But the gardener does more than the milliner. He not only effects kaleidoscopic changes of the same materials, but he sets in operation previously pent-up forces—forces which are made manifest in the phenomena of variation, adaptation and progressive evolution. The modern gardener, by means of incessant vigilance and adjustment of the conditions of environment, so far as he is able to do so, *cultivates* the plants committed to his charge so as to obtain the most healthy foliage, the finest flowers or the most luscious fruit according to his particular requirements. But cultivation is not everything. It improves the old, but it does not create the new. Selection, again, by which the gardener profits much, does not in all cases result in absolute novelty, but only in enhanced quality, a lessened amount of variability and a greater degree of fixity or constancy. A seedsman's "stock" of broccoli, or whatever it may be, is carefully "selected" by the choice and retention of what is required and by the rejection or elimination of what is not desired. The "rogues," that is the plants which do not come up to the high standard of perfection, are ruthlessly destroyed. By these procedures, carried on year by year, the stock at length becomes almost absolutely pure, and, what is more, it is kept so because the tendency to vary has become quiescent. Alter the conditions, exercise less vigilance, variation will again set in and the stock become correspondingly deteriorated. Cultivation, selection and elimination tend to preserve the old rather than to create the new.

Novelty in garden plants, apart from the direct importation of new species from foreign countries, is secured in various ways, such as the conservation or selection of variations which originate naturally. By repeated selection and elimination the desired variation is, as we have just said, finally "fixed." It becomes constant and capable of reproduction by seed. Another method of obtaining novelties is by the observation, retention and propagation of bud-variations or sports. A third and most effectual means is secured by the practice of cross-breeding.

Variation in some degree is almost universal; no two leaves on the same branch are alike, the peas in a pod really contradict the meaning of the proverbial adage, for, instead of being strictly alike, they are more or less different. But the discontinuous variation, the "sport" proper, as it is understood in gardens, is the representative of a more pronounced degree of variation—one that occurs suddenly, or at least its earlier manifestations are so inconspicuous as to be overlooked. It appears simultaneously in widely separated areas. It is mysterious in origin as it is striking in appearance. No doubt in many cases this sporting is a reversion to some ancestral condition, or is due to a separation of previously amalgamated characteristics, but what brings about the separation is a mystery. In any case, the gardener has little or no control over the phenomena of sporting; he does but avail himself of what nature provides him without any effort of his own.

It is a very different thing with cross-breeding. The larger number of "new garden-plants" at the present day are due to intentional cross-pollination or fertilisation. All degrees of this process occur from the union of male and female elements from individuals that present the least degree of distinctiveness up to the combination of the sexual elements in plants so wide apart as to be, for practical purposes at any rate, placed in distinct genera, and in one recorded case in a distinct order. Bigeneric hybrids have been recorded between *Philesia* and *Lapageria* (=Philageria × Mast.), between *Urceolina* and *Eucharis* (=Urceocharis × Mast.), between *Rochea falcata* and *Crassula coccinea* (= Kalorochea × Veitch), *Libonia* and *Sericographis* (= Sericobonia ×), between *Montbretia* and *Tritonia*, between numerous genera of Gesneraceæ, between *Scilla* and *Chionodoxa* (=Chionoscilla ×). Amongst orchids no fewer than 150 bigeneric crosses are recorded (Hurst, in *Journal* of the Royal Horticultural Society, 1900, vol. xxiv. p. 102).

In 1849 Donckelaar, the younger, the curator of the Botanic Garden at Ghent, raised a hybrid out of *Gesnera discolor* by pollen of a Gloxinia. This was called *Gesnera Donckelaariana* by Lemaire in the Jardin Fleuriste (1854), t. iv. p. 382. The good faith of the gardener was needlessly and unjustly impugned, and the hybrid nature of the plant was doubted by Decaisne, as was not unnatural at that time. But now that, as we shall presently see, the gardener has succeeded in actually producing by art the same form that exists in nature, there is no more occasion for scepticism.

Decaisne suggested that Donckelaar's plant was no hybrid, but a new species accidentally introduced with other species of Gesneraceæ. This view received confirmation some years later when Messrs. Veitch received from Colombia a plant which on flowering presented all the characteristics of *Gesnera Donckelaariana*. This plant was figured and described as a species by Sir Joseph Hooker in the *Botanical Magazine*, t. 5070 (1858). Several years afterwards (in 1894) Messrs. Veitch produced a hybrid between *Gesnera pyramidalis* crossed with pollen of Gloxinia "Radiance." This received the name of "Gloxinera ×," and is a sufficient proof that bigeneric hybrids may occur in Gesneraceæ. The Gloxinera was figured and described by Mr. J. Weathers in the *Gardeners' Chronicle* (February 2, 1895), and formed the subject of an interesting note from Count de Kerchove de Denterghem in a subsequent number (February 9, 1895, p. 175).

Many other bigeneric hybrids are recorded among the Gesneraceæ, but, until botanists have agreed as to the limitations and nomenclature of genera in this order (which they are far from having done at present), we must suspend our judgment as to the precise status of the numerous hybrids that are alleged to have been raised. For an account of them up to the time of publication, the reader may be referred to Mr. Burbidge's excellent work on "Cultivated Plants, their Propagation and Improvement" (1877), and to Dr. Focke's "Die Pflanzen Mischlinge" (1881), p. 326 *et seq.*

A still further degree of hybridisation is recorded in Maund's "Botanic Garden" (v. p. 468), where a cross from *Digitalis ambigua* (Scrophulariaceæ) by pollen of *Sinningia speciosa* (Gesneraceæ) is described. This, then, was a biordinal hybrid.

Fertile hybrids, the existence of which was once denied, are now too numerous to admit of further doubt. Mr. Hurst, *l.c.*, cites the occurrence of such plants in ninety distinct genera and only four in which the hybrids are quite infertile. Ninety per cent. of some forms of tuberous Begonias come true from seed, as is recorded in Mr. Lynch's excellent paper on the evolution of plants in the *Journal* of the Royal Horticultural Society (vol. xxv. 1900, p. 24). In that paper numerous illustrations are adduced to show that some garden hybrids, perhaps we might say a large proportion, "come true from seed," that is, the parental characters are reproduced in the progeny as markedly as in the case of any so-called species. Bigeneric hybrids are sometimes equally fertile. For instance, there are two Iridaceous genera, Montbretia and Tritonia, so distinct one from the other that they have always been considered as separate genera. Now the plant called *Montbretia crocosmiaeflora* × by Lemoine was raised by that eminent French gardener between *Tritonia aurea*, which furnished the pollen, and *Montbretia Pottsii* as the female parent. This is what M. E. Lemoine says in the volume to which we have just referred (p. 128):—

"It is generally admitted by all that hybrids are, as a rule, either absolutely barren or at most produce descendants as lacking in number as they are also in vigour and in reproductive qualities. Now *Montbretia crocosmiaeflora* × is a hybrid, and by no means an ordinary hybrid, for it is one of the very small group of bigeneric hybrids, its two parents ranking as species of different genera, and yet it has given birth to a long line of vigorous and fertile plants." This hybrid produces seed naturally, but as the progeny is almost identical with the parent form there is no particular object in the gardener raising such seedlings. But when the flowers of this hybrid are pollinated, by pollen taken from either of the original plants, then modification sets in and these modifications have become fixed (see p. 129).

Chionoscilla ×. The hybrid genus between Chionodoxa and Scilla, which occurs spontaneously when the two plants are grown together, is reported by Hurst to have produced fertile seeds.

Whether the facts that some of the so-called genera not only interbreed but "come true from seed" are to be taken as proofs against their autonomy as separate genera or not is a point of the highest interest, to which we can only allude, but which we cannot here discuss. We must be permitted for our present purpose to set aside theoretical considerations and to look on both species and genera as convenient subdivisions necessitated by the requirements of classification, but which, though probably so, are not yet proven to be phylogenetically "natural." All that we are concerned here to assert is that the gardener has succeeded in producing forms as distinct one from another as, often far more so than, those which we call species, and even genera, and which physiologically as well as morphologically "behave" in the same way that species do.

Tuberous Begonias furnish a case in point. They are no older than, scarcely so old as, the middle of the last century. Their history is perfectly well known. They have grown, as it were, under our very eyes. Were it not so there is no botanist who, seeing them for the first time, but would call them new species and think himself very fortunate in getting new species with such definite and easily recognisable marks of distinction. A distinguished French botanist, the late M. Fournier, even constituted a new genus, Lemoinea, to receive some of these widely divergent forms.

But, some will say, these creations of the gardener's skill are not permanent; alter the conditions and they will disappear. Moreover, they can only be propagated by division and not by seed. Were these objections universally true they would, of course, be fatal to our contention. But they are not universally true, and those that are true are just as applicable to natural species. Some at least, as we have seen, have a high degree of permanence, and many are capable of reproduction from seed.

It must not be supposed that these hybrid productions are all of artificial origin. So far back as 1852, Weddell enumerated, in the *Annales des Sciences Naturelles*, numerous natural bigeneric hybrids, and, of course, hybrids between species are now known to occur frequently among wild plants. But what is very interesting in this connection is the fact that gardeners have, over and over again, demonstrated the hybrid nature of certain wild plants by actually producing them artificially. The younger Reichenbach, from his great knowledge and experience, asserted that several orchids examined by him were of hybrid origin. He arrived at his conclusions solely from the observation of morphological characters. But Veitch and many others have since actually created in their orchid houses, by means of cross fertilising the two species, the same form that occurs in nature. They have proved by demonstration what Reichenbach merely conjectured from appearances. An enumeration of these orchid hybrids that have been produced in gardens is given by Mr. Rolfe in vol. xxiv. of the *Journal* of the Royal Horticultural Society, p. 188. Years before Reichenbach, Dean Herbert came to a similar conclusion as to the hybrid nature of certain Pyrenean narcissi, and he too proved the accuracy of his opinion by producing the hybrid form by artificial means. In our own times, Engelheart is doing the same sort of work and arriving at the same conclusions.

In the last class of cases, the gardeners have, as we have said, succeeded in reproducing the identical form that occurs in nature, and that form, of course, cannot be considered in any sense as a *new* garden-plant. But in the other cases mentioned, such as the Begonias, the Streptocarpus, the Clematis, &c., forms have been produced which have not, and could not have, any counterpart in nature. Some of the Andine Begonias very possibly hybridise naturally because they grow in proximity, or at no very great distance from each other. But what are we to say to the new "race" or "species," as we might term it, produced in gardens by fertilising the descendants of these South American Begonias with one discovered in Socotra by Prof. Bayley Balfour? It is hard to conceive of the possibility of a natural hybrid in this case, but, as artificially produced by the gardener, it is one of the greatest ornaments of our hot-houses and much more distinct from other "species" than most of the South American forms among themselves. It is true that in this case, up to this time, the flowers have been mostly sterile, but there are not wanting indications that the sterility may be naturally replaced by fertility, whilst it is certain that the gardener will discover the means to counteract the present nearly barren condition.

It would be easy to multiply instances wherein the gardener has produced new forms morphologically, and in some cases physiologically, worthy of specific or even of generic rank, but it is unnecessary to cite more, as the fact admits of no dispute. We have alluded to them here for the sake of illustrating one category of "new garden plants."

A point of much practical importance arises with reference to the names that should be given to these garden productions. The Kew list to which we have referred takes the names as they are published in the gardening journals, which in their turn copy them from the labels or the catalogues of the horticulturists. The journals are duly cited in the Kew list, but in no case is the author's name mentioned.

In the majority of instances this is the only course that could be advantageously followed, for the names are generally given without adequate research and with no reference to system. They are, in fact, the outcome of the nomenclator's fancy solely. But in many cases the plant is authoritatively described in the gardening periodicals, and when that is the case the customary citation might with advantage be made in the Kew list.

One most objectionable practice the gardeners have, and that is of imitating the names given by botanists *secundum artem*. In the eyes of the scholar, botanical nomenclature is mostly barbarous, but garden nomenclature is too often ludicrous. It is more than that, it is misleading. A botanist ignorant of the history of a garden plant and finding it provided with a Latin generic and specific name would naturally suppose that he had to deal with a species properly described and recorded, and would waste his time and patience in fruitless search unless by good fortune he lighted on the Kew *Bulletin*.

But if some sort of provisional name could be given to plants of garden origin or to plants of unknown status, such name to be so framed as not to give rise to misapprehension, horticulture would not suffer and science—at least indirectly—would be the gainer.

The Royal Horticultural Society has, at various times, endeavoured to grapple with this evil, and has even formulated a code of rules to be followed by the horticulturists when introducing "new" plants to the notice of the Society or the public. The rules are excellent, but they are far more frequently honoured in the breach than in the observance, and the Society seems powerless to enforce its own precepts even in its own records. The alliance of old custom with new developments, however anomalous, seems likely to persist in the future as it has done in the past. The Kew publications to which we have referred are invaluable to the student by lessening the difficulties of research and neutralising the anomalies of which mention has been made.

THE PHOTOGRAPHIC CHART OF THE HEAVENS.[1]

IT is to be regretted that a whole year has been allowed to intervene between the meeting of the International Committee charged with the construction of the photographic chart of the heavens and the official publication of the proceedings of the members, since the interest that would otherwise attach to the utterances of so many expert astronomers in conference assembled is materially lessened by the delay. Doubtless the collection of proofs from sources so scattered and so distant demands a long time, but the most careful and praiseworthy desire to secure accuracy might have been satisfied with a shorter period. Two very evident drawbacks result from this method of treatment. Not only have more or less complete statements appeared in various scientific journals, but the reports on the amount of progress effected by the various participants in the scheme refer to a twelvemonth since and are already ancient history.

But, on the other hand, it is abundantly evident that these meetings, held from time to time, perform a very useful work wherever widespread cooperation is necessary. They not only afford evidence of the earnestness of purpose and determination to successfully prosecute the scheme, that originated under the auspices of the late Admiral Mouchez, but they supply the means of most readily combining the activities of many observatories to secure a common aim. The readiness with which so many astronomers acceded to the request to undertake the observations of Eros, and the adoption of a uniform plan of wide-reaching extent, could scarcely have been effected in the time at disposal without personal intercourse and mutual encouragement. It is true that the observations have all been made and much of the reduction completed before we get the official report, but this in no way detracts from the value of the results immediately obtained, while the proceedings of the Conference will remain as a valuable historical document bearing on the progress of astronomical science.

To the general methods of observation of Eros and the success which has attended the scheme we have already referred (NATURE, vol. lxiii. p. 502), and may pass the matter aside with the reassuring reflection that the latest reports fully confirm the success that was anticipated from the earlier measures. Of the degree of completeness accomplished in the photographic surveys of the heavens it is not easy to form a very exact notion, owing to no tabular statement accompanying the report and the varied methods of description adopted by the various authorities, but the following table will exhibit fairly accurately the amount of progress reported up to the date of the meeting:—

Limits of Zone in declination	Observatory	Number of plates for catalogue	Number of plates for chart	Number of plates measured
90° to 65°	Greenwich	1106	1076	608
64 ,, 55	Rome (Vatican)	476	106	15
54 ,, 47	Catania	Complete	None	36
46 ,, 40	Helsingfors	Complete	⅓	380
39 ,, 32	Potsdam	Complete	None	(100,000 stars)
31 ,, 25	Oxford	Complete	None	736
24 ,, 18	Paris	Complete	97	650
17 ,, 11	Bordeaux	402	17	293
10 ,, 5	Toulouse	½	45	⅛
4 ,, −2	Algiers	Complete	97	497
−3 ,, −9	San Fernando	Complete	596	145
−10 ,, −16	Tacubaya	746	None	203
−17 ,, −23	Santiago	(Aban	doned)	
−24 ,, −31	La Plata	(Aban	doned)	
−32 ,, −40	Rio	(Aban	doned)	
−41 ,, −51	Cape	Complete	Complete	126
−52 ,, −64	Sydney	Complete	(Greater part)	
−65 ,, −90	Melbourne	900	Complete	

Of the plates for the chart it is intended that there should be two series, made respectively with one exposure of an hour and three exposures of half an hour each. The word "complete" in the chart column is meant to apply to one of these series, but Sir David Gill has made considerable progress with the second series. The arrangements made for supplying the lacunæ caused by the South American observatories finding themselves unable to fulfil their engagements have already been reported (p. 335).

To judge from the number of papers presented on the determination of photographic magnitude, this subject still seems to occupy a large share of the attention of the Committee—larger, indeed, than to an outsider the subject seems to warrant. On the occasion of the meeting in 1896, the committee decided that the several observatories were at liberty to determine the photographic magnitude, either by estimation or by measurement, simply stipulating that whatever system was adopted it should be one capable of precise definition and permit

[1] "Réunion du Comité international permanent pour l'exécution de la Carte photographique du ciel, tenue à l'Observatoire de Paris en 1900." (Paris: Gauthier-Villars, 1900.)

the scales adopted to be reduced to a common system. This seems to give sufficient latitude, but, nevertheless, at the eleventh hour, no less than five different papers are presented on this vexed question of magnitude. Among other papers forming the annexe is a short but interesting note from the Astronomer Royal on the number of stars found on each of the plates devoted to photographing the Polar Cap, with a comparison with the numbers comprised in the Durchmusterung and the accurate catalogues of the Astronomische Gesellschaft. The totals are as follows :—

Number of stars measured on the plates	58,176
Number of stars to the square degree	70·0
Number of stars in Argelander's Durchmusterung	9979
Ratio of photographed stars to Bonn D.M. ...	5·83
Number of stars in A.G.C. Catalogues	4966
Ratio of photographed stars to A.G.C.	11·7

If the number of stars approximately increases as the magnitude diminishes, the ratio here given would point to the faintest stars on the plate being 1·9 mag. fainter than Argelander's faintest stars, or well covering the eleventh magnitude, originally assigned as the limit to which the catalogue should extend.

Since writing the above, M. Lœwy has published very complete details showing the approximate times of observation of the planet Eros at no less than forty-six observatories where the work has been undertaken. The energy displayed is of the most gratifying character, and the final result will no doubt demand a degree of confidence commensurate with the labour that has been bestowed on the undertaking. The work is shown to be one of gigantic magnitude, and M. Lœwy displays considerable hopefulness in suggesting that two years may see it completed. Several other papers, all devoted to securing accuracy and homogeneity in the final reductions, also appear in this brochure. We may especially call attention to a paper by the Director of the Paris Observatory on the degree of precision that the photographic measures possess, and of the success that is likely to attend the adoption of the scheme for driving the equatorial at various rates depending on the amount of geocentric motion of the planet itself. The additional matter supplied by the Paris authorities is of a highly interesting character to which we hope to do justice later, when complete details from the various authorities are published.

THE COLORADO POTATO BEETLE.

THE official announcement by the Board of Agriculture of the appearance of the Colorado potato beetle swarming in a potato field at Tilbury is a very serious matter, for we have no wish to see another insect pest added to those with which our agriculturists already have to contend. It is satisfactory to know that the Board took instant measures to cause the destruction of all the crops within the infested area ; and as the surrounding neighbourhood has since been searched in vain for any further traces of the insect, it is confidently hoped that the measures taken for its timely extirpation have proved successful.

The beetle is about half an inch long, and slightly oval in form. The wing-cases are longitudinally and alternately striped with black and yellow, and the wings are red. The grubs, which feed on a great number of other wild and cultivated plants besides the potato, are orange or reddish, with a row of black spots on each side. The oval yellow eggs are laid in clusters.

The insect was so destructive in North America some years ago that great fears were entertained of its spreading to Europe ; and at that time was passed the Destructive Insects Act, according to which every person meeting with the insect is bound, under a penalty of 10*l*., at once to inform the police, who in their turn must notify the local authorities, who must communicate by telegraph with the Board of Agriculture.

It must be remembered that, if there is danger of an injurious insect establishing itself in a country, instant action is as necessary as in the case of a threatened epidemic.

W. F. KIRBY.

PROF. BARON ADOLF ERIK VON NORDENSKJÖLD.

WHEN a man who has spent an earnest and useful life reaches the mature age of threescore years and ten, it must be a relief to those near and dear to him when his last days are not spent in suffering. The great Swedish explorer's end was in this wise. "His death," writes his nephew, Dr. Otto Nordenskjöld, "was absolutely sudden ; the same day he was working in his laboratory, occupied with great plans in his mineralogical and chemical work."

Baron Adolf Erik von Nordenskjöld was born at Helsingfors, the capital of Finland, on November 18, 1832, the third in order of seven children. His father, Nils Gustav Nordenskjöld, descended from a scientific family, and, himself an ardent naturalist, was chief of the Mining Department of Finland. Nils Gustav was a most distinguished mineralogist, and his work brought him into communication with the most eminent mineralogists and chemists of his time in France, Germany, and Britain. He travelled as far as the Urals, and on many of his journeys he was accompanied by his son, Adolf Erik von Nordenskjöld, who as a boy became an industrious collector of minerals and insects. He acquired great skill in collecting minerals and in the use of the blow-pipe, which his father handled with a masterly skill, unknown to most of the chemists of the present day. Thus, both by inheritance and by the influence of environment, Nordenskjöld had opportunities allotted only to the few, but which were taken the greatest possible advantage of. His early education was from private tuition, after which he was sent to "gymnasium" at Borgo, a connecting-link between school and university. Here he distinguished himself, as the rector expressed it, "only by absolute idleness." He was marked in his certificate "unsatisfactory" in nearly the whole of the subjects. His parents were judicious enough not to attach any importance to this well-deserved mishap. His private tutor was removed ; and with five silver roubles Nordenskjöld had to seek modest board and lodging, and got full liberty to manage his studies in his own way. "Self-respect," he says, "was thus awakened. I became exceedingly industrious, and was soon one of those then attending the gymnasium who obtained the best reports."

Nordenskjöld entered the University of Helsingfors in 1849, devoting himself chiefly to the study of chemistry, natural history, mathematics, physics, and, above all, of mineralogy and geology. He took charge of the rich mineral collection of Feugard, and made many excursions. In 1853 he accompanied his father on a mineralogical tour to Ural, when he planned an expedition to Siberia, which the Crimean War prevented him from carrying out. On his return he wrote, as his dissertation for the degree of licentiate, a paper "On the Crystalline Forms of Graphite and Chondrodite," which was discussed under the presidency of Prof. Arppe on February 28, 1855. At this time he published "A Description of Minerals found in Finland," "The Mollusca of Finland" with Dr. E. Nylander, and shorter papers in the "Acta Societatis Scientiarum Fenniæ." During this time he was appointed Curator of the Mathematico-Physical Faculty and to a post at the Mining Office with inconsiderable pay. Before he received his second quarter's salary he was removed from these offices at the instigation of the Governor-General, Count von Berg. This was done on account of some political speeches of a frolicsome nature made at a tavern in Thölö. Some of the students were rusticated for a term, and Nordenskjöld got double dismissal without further ceremony. He bore his misfortune with philosophic calmness, and betaking himself to Berlin worked in Rose's laboratory at mineral analysis.

Next year he returned to Finland, and received the Alexander stipend for a tour of study through Europe, and obtained his degree of master and doctor. At this "graduation" ceremony the Universities of Upsala and Lund had a deputation that was received in a most cordial manner, and Nordenskjöld proposed a toast "to our memories all, and to the time that has been and the time that shall come, if only it does not bring Finland's fall, a toast to the days of memory that have fled and the hope that still remains." This speech the tyrannical von Berg regarded practically as high treason. Nordenskjöld treated the whole affair with contempt, but had to leave Finland and go to Sweden. The Russian Government, moreover, deprived him of the right of ever holding office in Helsingfors University. Further persecution followed, and von Berg actually urged in the Senate, Nordenskjöld's exile for having entered foreign service without asking permission of the Russian Government. After 1862, however, when von Berg's term of office had expired, he was allowed to go to Finland whenever he pleased.

Nordenskjöld's first visit to the Polar regions was with Torell to Spitsbergen in 1858, with whom he went as geologist. At Belle Sound he found Tertiary fossil plants which formed the first of the extensive geological collections brought home by subsequent Swedish expeditions; besides these he also obtained fossils from the Carboniferous and Jurassic formations, as well as fine minerals from the limestone veins on the Norways, Cloven Cliff, &c. On the death of Mosander, after his return, he was appointed professor and director of the Riks-Museum, Stockholm. It was because he held this post that von Berg wished to have him declared an exile. By means of energetically purchasing and collecting, and in consequence of the extraordinary richness of the Scandinavian peninsula in rare and remarkable minerals, the Mineralogical Museum at Stockholm, with help of the collections, valuable in certain directions, which have existed from Mosander's time, has in this way become one of the most considerable in Europe. In 1860 his old friend J. J. Chydenius, afterwards professor of chemistry at Helsingfors, joined him as collaborateur, and they made many excursions together. In 1860 his mother died, but he was not permitted to visit Finland even to bid her a last farewell. In 1861 he again visited Spitsbergen with Torell, on which occasion he had an opportunity of surveying the northern part of that archipelago, clearing up the main points of the geognosy of the country. This expedition was the first foundation of a true knowledge of the natural history of the Polar countries. In July 1863 he married Anna Mannerheim, a Finnish lady, and abandoned all thoughts of further Arctic journeys. "Circumstances, however," he says, "so arranged themselves that just from this time they were resumed by me, and on a greater scale than before." In 1863 he was asked by the Royal Academy of Sciences of Sweden to lead an expedition to Spitsbergen in the place of K. Chydenius, who was ill. He asked Docent Duner and Dr. Malmgren, of Lund, to join him. Starting in the spring of 1864, he completed the preliminary part of the survey for the arc of meridian, mapped the southern part of Spitsbergen, and collected new data as to fauna and flora. The sea was very free of ice; but an attempt at a high latitude was frustrated by meeting with seven boats with the crews of three wrecked walrus sloops, which compelled immediate return to Norway. In 1867 he visited Paris, having been commissioned, along with Prof. A. P. Ångström, to compare a normal metre and a normal kilogram, which had been made for the Swedish Government, with the prototypes preserved in the Conservatoire des Arts et Métiers.

Through Count Ehrensvard, Governor of Gothenburg, funds were raised, after several unsuccessful attempts, from Dickson, Ekman, Carnegie, &c., for another Polar expedition. State-Counsellor Count Platen, head of the Marine Department, took a special interest in the plan, and the iron steamer *Sofia* was placed at Nordenskjöld's disposal by the Government. On September 19, 1868, the *Sofia* attained the highest northern latitude which any vessel can be proved to have attained in the old hemisphere—namely, 81° 42′ N. The name of Mr. Oscar Dickson is always associated with that of Nordenskjöld; it was he who had contributed most liberally to the expedition of 1868, and Nordenskjöld was overjoyed when he voluntarily offered to equip another expedition to the same region. It was determined that the new expedition should have for its object to winter on the north-east coast of Spitsbergen, in order thence to push northwards in sledges on the ice. After a long set of inquiries as to whether dogs or reindeer should be used for draught purposes, Nordenskjöld decided upon reindeer. It was also decided, with Mr. Dickson's consent, that Nordenskjöld should go to Greenland to investigate the question of dogs, and this expedition was extended into a scientific one, three young Swedish men of science accompanying him. On this occasion he made a long journey into the interior of Greenland, almost equal in distance to that of Nansen undertaken some years later. Of this journey Nordenskjöld says: "I had here an opportunity of clearing up the nature of a formation which, during one of the latest geological ages, covered a great part of the civilised countries of Europe, and which, though it has given occasion to an exceedingly comprehensive literature in all cultivated languages, *had never before been examined by any geologist*." The same year, with some others, Nordenskjöld petitioned the Swedish Government to form a colony in Spitsbergen to work its mineral resources. This petition gave occasion for the Foreign Minister of Sweden to inquire of the Powers of Europe as to the annexation of Spitsbergen by Sweden. Russia alone objected, and Spitsbergen remains to the present day "No Man's Land."

The long-prepared new Polar expedition finally started in 1872. "The state of ice," says Nordenskjöld, "on the north coast of Spitsbergen was more unfavourable in 1872 than it had been at any time since the coast was frequented by the Norwegians." The reindeer escaped on the third day. The ship got frozen in on September 29, and the crews of six walrus sloops, which had also been frozen in, depended on Nordenskjöld for subsistence. Thus Nordenskjöld, instead of having twenty-four mouths to feed, was confronted with the almost insuperable problem of feeding 125. Seventeen of the walrus hunters, therefore, under the veteran Mathilas, reached Cape Thorsdem by boat, 200 miles distant, where they found all necessities at the quarters of the Swedish colony. Fortunately, two vessels escaped in November and took the crews of four vessels with them; but two men who remained died that winter. Nothwithstanding all this, the expedition yielded important scientific results, not the least important being the discovery of cosmic dust on the Polar ice. Extensive journeys along the north coast and across the inland ice of North-east Land were also made. In spite of the heavy expenses incurred in this voyage, Mr. Oscar Dickson declared that he was willing to "go on."

During the next few years, with his help, Nordenskjöld worked at the opening up of the Yenisei and the Siberian seas, which culminated in his ever-memorable voyage, accomplishing the North-east Passage in 1878–79. The voyage of the *Vega* is still fresh in the minds of all. Leaving Tromsö on July 21, she rounded East Cape on July 18, 1879, less than twelve months afterwards. The *Vega* found the Kara Sea free; and since that sea was so favourable, a considerable time was spent on dredging, sounding, and other scientific observations, including the re-mapping of the coast-line between Yenisei and Cape Sterlegof. Ice and bad weather detained him at Tainia Bay, but on August 19, the *Vega* rounded the northernmost point of Asia, Cape Chelyuskin. Next day the *Vega* was further north, namely, 77° 45′ N., which proved to be the most northerly point reached. At the Lena Delta, the *Lena*, which accompanied the *Vega* so far, turned southward up the river, and Nordenskjöld continued his voyage toward Bering Strait. On September 12, progress was stopped at the "North Cape" of Cook, where he turned back to Bering Straits in 1778, and Nordenskjöld was forced to winter off Pitlekai in 67° 07′ N., 123° E. Systematic scientific observations were carried on during the whole winter, spring, and following summer, till on July 19 they were released, and two days later rounded the eastern extremity of Asia with flying colours. On September 2, 1879, Nordenskjöld dropped anchor at Yokohama, whence the whole civilised world received the news that this man had accomplished what had so often been attempted during three centuries. For this brilliant exploit, Nordenskjöld was awarded a magnificent reception throughout Europe, and many honours were showered upon him, including his elevation to the rank of Baron in the Swedish Peerage. It is from the complete and striking success of this expedition that Nordenskjöld became popularly world-renowned.

In 1883 he undertook a second expedition to Greenland, penetrating further into the interior than any other explorer.

His success rested on the solid basis of his scientific instinct and training, and of his indomitable will and courage. It is to him that we owe the first real efforts at undertaking scientific research in the Polar regions, especially from the geological and mineralogical aspects.

His researches outside the Polar regions were also important. He discovered uranium in many varieties of coal, and he showed that fresh water could be obtained anywhere in Scandinavia at a depth of 100 feet through the Archæan rocks. This has been proved in 400 cases to be correct, and has been of great advantage to pilots, fishermen, lighthouse keepers, &c., living on small islands without water, and also for many factories. He remained a politician all his life. On account of refusing to suppress his opinions in this direction, he was rejected in 1867 as a candidate for the chair of mineralogy and geology in Helsingfors University, although he was unanimously recommended. As the son of a Swedish nobleman, he sat and voted in the Swedish House of Nobles; but, although so intimately associated with Sweden for the greater part of his life, he always referred to Finland as his "dear Fatherland." In his latter days he interested himself in South Polar exploration, and it must have been pleasing to him to know that his nephew was about to lead an expedition to the Antarctic regions.

W. S. BRUCE.

NOTES.

THE appointment of the Royal Commission on Tuberculosis was announced in Tuesday's *Gazette*. The Commission is composed of Sir Michael Foster, K.C.B., F.R.S., Prof. G. S. Woodhead, Prof. S. H. C. Martin, Prof. J. McFadyean, and Prof. R. W. Boyce. It is appointed to inquire and report with respect to tuberculosis:—(1) Whether the disease in animals and man is one and the same; (2) whether animals and man can be reciprocally infected with it; and (3) under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances favourable or unfavourable to such transmission.

THE International Engineering Congress was opened at Glasgow on Tuesday with an address by the president, Mr. James Mansergh, F.R.S. Referring to the value of the work of settling standard sections of important constructive materials, Mr. Mansergh remarked that this matter had been taken in hand by a joint committee of the Institution of Civil Engineers, the Institution of Mechanical Engineers, the Institution of Naval Architects, and the Iron and Steel Institute. Sir Benjamin Baker, with a specially-selected sub-committee, had charge of bridge and general building construction; Sir John Barry, with similar assistance, of railways; Mr. Denny, of shipbuilding; and Sir Douglas Fox, of rolling-stock. In the hands of these eminent engineers the work would be well handled. The address concluded with brief references to some of the chief subjects to be brought before the various sections of the congress. After the address members of the congress dispersed to the meeting rooms of their sections, where addresses were delivered by the sectional presidents, and papers were read.

THE forty-sixth general meeting of the German Geological Society will be held at Halle on October 4–7.

WE regret to announce that Dr. Charles Meldrum, C.M.G., F.R.S., late Director of the Royal Alfred Observatory, Mauritius, died on August 28 in his 80th year.

IT is stated that the exhibits of the German chemical industry at the Paris Exposition valued at 30,000*l.* have been presented to the Technological Institute of the University of Berlin.

THE Vienna correspondent of the *Times* states that the Emperor Francis Joseph has addressed an exceptionally cordial autograph letter to Prof. Edward Suess, the eminent Austrian geologist and politician, on his retirement from the Vienna University. The Emperor expresses his high appreciation of the work done by Prof. Suess in science, as an academic teacher, and as a public man, especially in the promotion of sanitary reform.

A TELEGRAM received by the American Consul at Christiania from the secretary of Mr. Baldwin's American Polar Expedition at Hammerfest, states that the Norwegian steamship *Frithjof*, which is one of the vessels employed by Mr. Baldwin, has returned to Hammerfest after fitting out and provisioning the expedition in Franz Josef Land. The expedition was landed at Cape Ziegler; when the *Frithjof* sailed from that point the conditions were favourable for pressing northwards, and Mr. Baldwin intended to begin his advance the next day.

THE Australasian Ornithologists' Union has been successfully inaugurated, and the first general meeting will be held at Adelaide in October or November. The objects of the Society are "the advancement and popularisation of the science of ornithology, the protection of useful and ornamental avifauna, and the editing and publication of a magazine or periodical, to be called *The Emu*, or such magazine or periodical as the Society may from time to time determine upon." Colonel W. V. Legge is the president-elect, and Mr. D. Le Souëf, Zoological Gardens, Melbourne, is the honorary secretary.

IN connection with the proposed Pasteur statue for Paris, the Paris correspondent of the *Chemist and Druggist* states that an attempt is being made to make it a national monument. The idea is that every Frenchman and resident in France should become a subscriber, and amounts from a halfpenny upwards will be received. Subscription-lists have been distributed in large numbers amongst heads of business-houses, manufactories, and Government offices, inviting them to collect sums, however small.

THE New York correspondent of the *Times* reports as follows upon experiments made at Havana to test whether yellow fever is carried by mosquitoes:—"Out of eight persons bitten by infected insects three have died, three have the fever and will possibly recover, one is not affected, while as regards the remaining case it is too early to make a diagnosis. The physicians are shocked at the result of the experiments. It was supposed that direct infection from mosquitoes caused only a mild form of the disease, and was a safe means of making the subjects immune. It is now definitely known that a man bitten by an infected mosquito after being inoculated with the serum introduced by Dr. Caldas, a Brazilian expert, has developed a genuine case of fever."

MAJOR RONALD ROSS, F.R.S., has just returned to England rom West Africa, where he has been organising a campaign against mosquitoes and malaria. After inaugurating the campaign at Sierra Leone, Major Ross went to Lagos, where the Government actively concerns itself with all matters affecting the health of the community. In welcoming him to the colony, the Governor, Sir William Macgregor, referred to the measures taken to promote sanitary conditions, and thus increase the industrial prosperity of West Africa. Major Ross, in thanking His Excellency, said that he had been on the point of believing that his countrymen were becoming an unscientific and unpractical people. More than two years ago the fact that malarial infection is communicated by mosquitoes had been established by the most stringent scientific and experimental proof; and yet to his knowledge practically nothing had been done by his countrymen to act on this new information, in spite of its economic importance. He had, therefore, accepted with alacrity the offer of a large sum of money and other facilities from a generous philanthropist, and from Mr. A. L. Jones, Mr. John Holt, and others in England, to pay the expenses of practical work against malaria in Sierra Leone. This work had been commenced with every promise of success by his friend, Dr. Logan Taylor, and he had, therefore, felt himself free to proceed to Lagos to watch the work being done there. He was delighted to find that his pessimistic attitude was not justifiable as regards Lagos. He strongly eulogised everything that was being done against malaria by Sir William MacGregor, himself a distinguished member of the medical profession, by his most able friend, Dr. Henry Strachan, and by the enlightened medical profession and the Ladies' League in Lagos. He had witnessed the rapid and successful filling up of marshes by sand from the lagoons, and the rational utilisation of gaol prisoners for this useful work. He had inspected numerous houses rendered mosquito-proof by fine wire netting, which, while it did not exclude the breeze, as he expected it would, did exclude insects and damp, much to the comfort of the inmates. He highly commended the efforts of the Government to induce their officials and others to take quinine—a prophylactic which was much neglected in consequence of ignorance and faddism. Before the departure of Major Ross for Accra, Mr. C. Tambaci and other leading merchants promised to place an annual subscription of 150*l.* in the hands of the Governor to pay for a "Mosquito Brigade" for Lagos.

IN an address on tuberculosis given at the autumnal conference of the Sanitary Inspectors' Association last week, Sir James Crichton Browne referred to the subject of the relation between bovine and human tuberculosis, and Dr. Koch's recent statements upon it. In the course of his remarks, he said:—"Private investigations and experiments, laudable and significant enough though they might be, would not meet the requirements of the case, and the country was entitled to ask that a thoroughly competent public tribunal should, after a searching trial, determine whether the restrictions on trade that had been proved to be unnecessary should be abolished, or whether still more stringent restrictions than hitherto should be enforced to prevent human tubercular infection from animal sources. Dr. Koch had discredited the Report of the last Royal Commission on Tuberculosis, which up to now they had regarded as a standard work of reference; and it seemed highly desirable that the Report should be officially confirmed or declared to be obsolete." It was afterwards unanimously resolved:—"That this Association is of opinion that it is desirable that a Government inquiry should be instituted into the question as to the identity or the non-identity of human and bovine tubercle, and that a copy of this resolution be sent to the Right Hon. Walter Long, President of the Local Government Board."

READERS of NATURE are aware that kites carrying meteorological instruments have been employed for several years at the Blue Hill Observatory, Massachusetts, in the studies of the atmosphere carried on there. Until recently, no flights were made in winds having rates of less than twelve miles an hour; but Mr. A. L. Rotch, the Director of the Observatory, has now used the common method of creating an artificial wind and raising kites in comparatively calm weather by motion of the earth-end of the kite string or wire, the motion in this case being obtained from a rapidly moving tug. The apparatus employed consisted of a portable windlass containing 3600 feet of wire, three Hargrave kites having a total lifting surface of 80 square feet, and an instrument for recording temperature, pressure and wind velocity and humidity. This outfit was installed on the upper deck of a tug in Massachusetts Bay on August 22. Two flights were made, and the greatest heights reached were 2630 and 2670 feet. With more wire and kites much greater heights could have been obtained. The natural wind varied between six and eleven miles an hour, and was much too light to elevate the kites and apparatus, but by steaming against the wind the velocity relative to the tug and kites was increased to between fourteen and nineteen miles an hour. In this artificial wind the kites rose easily, and so steadily that they could be let out from and hauled into hand without the slightest risk to kites or instruments. The kites were very sensitive to alterations of the course of the tug, and began to fall whenever the course varied 30° to 50° on either side of the mean direction of the wind. The experiment shows that meteorological records at great heights may easily be obtained during calms or very light winds by means of kites flown from a rapidly moving steamer; and that it is now possible for the observer and student to work uninterruptedly under almost all conditions of wind and weather.

THE Kew *Bulletin of Miscellaneous Information* for November and December 1899 has just been received. In spite of its belated publication, several of the contributions to it are noteworthy. Of current interest is a paper on the two West Australian woods, jarrah (*Eucalyptus marginata*) and karri (*Eucalyptus diversicolor*), which are now largely used, especially for wood paving. Over nearly all the world, and more particularly in England, these woods are in increasing demand. A Department of Woods and Forests has now been established, and its general usefulness as regards the control and management of the enormous natural wealth of the timber resources of the colony is beginning to be recognised and appreciated. Something over one million acres of forest land have now been leased from the Government for the purpose of acquiring the timber upon them. This is chiefly jarrah country, and embraces some of the finest forests of that particular kind of tree, which is the principal timber-tree in Western Australia. There are other timbers in the forests which are equally, if not more, valuable for their own special purposes, but for general constructive works, necessitating contact with soil and water, the timber of this tree stands foremost. The karri is not so well known as the jarrah owing to the limited area and, at present, comparative inaccessibility of its field of growth. It is the giant tree of Western Australia, if not of the whole Australian continent. For street blocking karri timber is most valuable, and for this purpose seems to be equal to, if not better than, the jarrah, in that its surface, by the wear caused by the traffic, does not render it so slippery for the horses' feet. As is well known, this timber is now largely used for London street paving.

SOME farmers believe that the moon has a direct effect upon vegetation, and that the time of sowing seeds should be regulated by the lunar phases. No accurate experiments appear to have been made to investigate this influence; and a note in the U.S. *Monthly Weather Review* points out that the belief is one that has come down to us from very early times, and began before accurate observations were recorded. Two proverbs relating to the influence of the moon upon vegetation, as handed down to us through folk-lore, read as follows:—

> "Go plant the bean when the moon is light,
> And you will find that this is right;
> Plant the potatoes when the moon is dark,
> And to this line you will hark."
> (*Dunwoody, Weather Proverbs.*)
>
> "Sowe peason and beans in the wane of the moone
> Who soweth them sooner, he soweth too soone."
> (*Werenfels, Dissertation upon Superstition*, 1748.)

Here are two different sayings as to the phase of the moon during which to plant: (1) a bright moon for beans and a dark moon for potatoes; (2) a waning moon for peas and beans. Another proverb states that sowings should always be made at the period of an increasing moon. Further astrological considerations are also often introduced, and if they were permitted to determine the time of planting seeds, farmers would find that there are only one or two full working days in a whole month when the moon and the signs are favourable. Fortunately, farmers as a class wisely busy themselves with seed-sowing when the soil (not when the moon) allows it, and have more faith in laborious cultivation, manure, rainfall and temperature than in lunar influence.

MR. J. HALL-EDWARDS, who was surgeon-radiographer to the Imperial Yeomanry Hospital, South Africa, described some of his experiences as to the value of Röntgen rays in warfare at the recent meeting of the British Medical Association. He found that the plan of obtaining the current for charging the accumulators from a dynamo connected with a belt to a foot motor of the bicycle type was altogether impracticable, as no one could work the bicycle arrangement long enough to be of much use. A small oil engine was used instead of the foot power, and worked very satisfactorily. As to the results of the introduction of Röntgen rays into military surgery, Mr. Hall-Edwards remarks:—"With the friendly aid of these rays, we are enabled to record the effects of small-bore projectiles under the various conditions which occur in actual warfare. We are enabled to localise the position of a bullet or other foreign body with absolutely scientific accuracy; and, if our present knowledge be used to its fullest extent, we can see the condition of the parts as plainly as we could do were the soft tissues composed only of transparent gelatine. These facts being recognised, it is easy to see that the application of the rays to military surgery must produce results of the greatest possible value for future guidance, and that their complete application in a great war—such as we are at present engaged in—must prove of inestimable service in increasing our knowledge upon this most important subject. Many of the time-worn, useless and dangerous methods of finding the whereabouts of hidden bullets may now be forgotten; for with these rays we have at our disposal an aseptic, scientific and absolutely accurate method of localisation, which may be improved, but which even now is as near perfection as our present knowledge can make it. There can be little doubt that, in the face of the new facts brought to light by means of these rays, military surgery will have to be rewritten, and the advance made will mark an epoch in its progress."

"I RETURNED, and saw under the sun, that the race is not to the swift, nor the battle to the strong," wrote the wise man. Writing in the same prophetic vein, M. J. de Bloch in the current *Contemporary Review*, and Mr. H. G. Wells in the *Fortnightly* for September, depict in graphic colours the transformation which the immediate future will witness in the methods of warfare. Both writers are convinced that the military tactics of the past are irretrievably dead. The effective soldier of the future will be a man whose capacity for individual action has been cultivated and developed. The day for all the picturesque accompaniments of war is done, and exhibitions of mere brute courage will be of no avail. Mr. Wells takes into account the resources which modern science has made available for the business of war, and proceeds to anticipate the most likely directions that future advances will take. Of one thing he leaves his reader in no doubt, victory is bound to be with the nation that most sedulously attends to the education of its people in the scientific method. The great war of the future will be fought by citizens familiar with destructive instruments of precision, who have learnt to utilise all the accessory helps which science is gradually perfecting. There will be few professional military men of the type of to-day in the ranks of the victorious nation. In Mr. Wells's words, "the warfare of the coming time will really be won in schools and colleges and universities, wherever men write and read and talk together. The nation that produces, in the near future, the largest proportional development of educated and intelligent engineers and agriculturists, of doctors, schoolmasters, professional soldiers, and intellectually active people of all sorts; the nation that most resolutely picks over, educates, sterilises, exports, or poisons its People of the Abyss; . . . the nation in a word, that turns the greatest proportion of its irresponsible adiposity into social muscle, will certainly be the nation that will be the most powerful in warfare as in peace."

WE have received a report by Prof. Elster on progress in the study of Becquerel rays, reprinted from Dr. Eder's photographic *Jahrbuch* for 1901. It is a summary of experimental work done in this direction subsequent to the report by the same author for the previous year.

A REPRINT from the *Proceedings* of the South London Entomological Society contains a paper on the ova of Lepidoptera, by Mr. F. Noad Clark. Mr. Clark has been highly successful in photographing these eggs, especially when account is taken of the difficulty of obtaining good photographs of opaque microscopic objects.

FROM the annual *Report* for 1900 we learn that the Botanical Exchange Club of the British Isles now has a membership of fifty. During the year 373 covers were sent in, 67 containing Rubi, 49 Hieracea, and 14 Euphrasiæ, the total number of specimens received and distributed being 4575. The report contains a large number of notes of new varieties, new localities, and records confirming the persistence of rare species and varieties in previously recorded habitats.

A THESIS recently presented to the Paris Faculty of Science by M. Henri Bénard deals with the cellular distribution of eddies produced in liquid films when convection currents are set up. Although the phenomena herein described have been previously recorded, but little appears to have been done in submitting them to systematic observation. These phenomena consist in the property that when a horizontal film of liquid has its lower surface heated to a higher temperature than its upper surface, the convection currents divide the liquid into a series of more or less regularly formed hexagonal cells, the liquid flowing down the sides and up the middle. The experiments have been made chiefly with spermaceti, various methods being adopted in order to make the cellular structure visible by the addition of solid particles. The distribution of motion is found to be permanent and stable, and M. Bénard has determined all the geometric, kinematic and dynamic elements of the motion.

Bulletin No. 44 of the Agricultural Department of Madras consists of notes on the domesticated cattle of that Presidency by Mr. J. D. E. Holmes, of the Veterinary Department. The various breeds found in this part of India are recorded and briefly characterised.

A RECENT issue of the *Proceedings* of the U.S. Museum (No. 1228) is devoted to the consideration of the relationships of the jumping-mice to the jerboas on the one hand and to Sminthus on the other. The author, Mr. M. W. Lyon, comes to the conclusion that the first-named animals typify a family (Zapodidæ) by themselves, and that in that family should be included the genus Sminthus, which was referred by Alston to the mice and rats (Muridæ). In No. 1227 of the same publication Mr. D. W. Coquillett discusses the classification of the flies (Diptera).

THE first part of a list of the birds in the Indian Museum, Calcutta, by Mr. F. Finn, has been received. Although this little work is nothing more than a classified list of species (containing in this part the families Corvidæ, Paradiseidæ, Ptilonorhynchidæ, and Crateropodidæ), with a record of the specimens by which each is represented in the Calcutta Museum, it has a considerable value to ornithologists on account of the inclusion of a list of "type" specimens. How extensive must be the series of such types in the Indian Museum may be inferred from the fact that there are no less than sixty-six in the Corvidæ and Crateropodidæ alone. Bearing in mind the liability to damage and decay of almost all natural history specimens in the climate of Lower Bengal, the question must suggest itself to all ornithologists whether it is advisable that such valuable specimens should remain permanently in Calcutta.

OUR American contemporary *Science*, for August 16, contains the report of a lecture on regeneration and liability to injury in animals, delivered by Prof. T. H. Morgan at Columbia University. In this lecture (which forms the first of a series) Prof. Morgan commences by discussing the common belief as to the existence of a definite relation between the liability of an animal to injury and its power of regeneration, and the idea that those parts of an animal most subject to injury are those in which the power of regeneration is most developed. With regard to the latter portion of the popular belief, Prof. Morgan has no hesitation in condemning it as unsound. The fact that in animals with "breaking joints" the regeneration may take place both above and below such joint is, he states, a sufficient demonstration of the falsity of the belief. With regard to the other part of the proposition, Prof. Morgan adduces evidence to show that the power of regeneration is characteristic of groups rather than of species; and that when exceptions do occur it is not in the case of forms specially protected from injury. "If this is borne in mind, as well as the fact that protected and unprotected parts of the same animal regenerate equally well, there is established, I think," says the lecturer, "a strong case in favour of the view that there is no necessary connection between regeneration and liability to injury."

TWO weeks ago announcement was made that the President of the Board of Trade had appointed a committee to inquire and report upon the means by which the State or local authorities could assist scientific research as applied to problems affecting the fisheries of Great Britain and Ireland. It was gratifying to record this sign of interest in the scientific aspects of our fisheries, and the appointment has not been made too early, for we learn, from a letter which Mr. W. Garstang contributes to the *Western Morning News* of August 28, that the Technical Instruction Committee of the Cornwall County Council has curtailed the grant for fishery purposes which it has been giving for the past few years, apparently as a prelude to further restrictions of the work done by the Sub-Committee for Fisheries. Perhaps the appointment of the Board of Trade committee will induce the Cornish authorities to reconsider their recent action, for they should see that the subjects which the committee have to consider are those which their own fishery expert has had under consideration since he began his investigations. Cornwall has in fact been doing what every local authority having fishery interests within its area ought to do; and to limit the scientific work it has instituted would be an unfortunate and altogether unsatisfactory conclusion of an enlightened policy. It is difficult to point to direct benefits received from such work, but the subjects of instruction and experiment carried on under the auspices of the Cornish committee ought to meet with the approval of far-seeing practical men. Our fisheries are declining at a very rapid rate, and scientific advice is needed to show how waste can be reduced and supplies increased. As Mr. Garstang remarks, there is no valid reason why biology, with suitable means and opportunities, may not do as much for our fisheries as chemistry and physics have achieved for our manufactures. "It should not be forgotten that the vast oyster fisheries of France at the present day are to a large extent the outcome of a commission given to a man of science, M. Coste, by the French Government exactly fifty years ago, when 'it is hardly an exaggeration to say there was scarcely an oyster of native growth in France.' Coste successfully introduced the Italian methods of culture into France, and his countrymen modified them to suit the local conditions, though years were spent in the needful preliminary experiments. No one to-day would assert that those years of experiment were ill-spent, although at the time their cost was doubtless greater than their immediate return."

"BRITISH RAINFALL" (for 1900) appears for the first time without the name of the late Mr. Symons, the editors of the rainfall records now being Mr. H. Sowerby Wallis and Dr. H. R. Mill. The subjects of special contributions to the new volume are the Ilkley flood of July 1900, and the development of rainfall measurement in the last forty years. In the latter article Dr. Mill gives an interesting account of the various kinds of rain-gauges which have been used, and states some of the general results obtained. Copper is generally adopted as the material for rain-gauges because it is not affected much by weather, its surface is smooth, and it is not easily broken. Ebonite is better, but it is more costly; zinc, though cheaper, deteriorates in the neighbourhood of towns or manufacturing districts. Dr. Mill suggests, however, that it might be possible to find a suitable substitute for copper among such substances as pure nickel, enamelled iron, and celluloid, with modern enamel paints. The size of the rain-gauge is immaterial, and the 5-inch gauge has been adopted as the standard because it does not collect an embarrassingly large or inconveniently small volume of water for measuring. The exposure and elevation of rain-gauges have formed the subjects of many experiments and reports, and Dr. Mill thus sums up the observations:—"The outcome of the whole matter is, that over a broad, flat surface, whether a natural feature of the ground like a plain, a plateau or flat-topped hill, or an artificial erection like a very extensive flat roof, increase of height produces no diminution in the amount of rain caught by a gauge having its mouth one foot above the surface on which it rests. But any abrupt change in the slope of the surface near the gauge, whether it be an embankment across a valley, a cliff, or a steep roof, or tower, allows the wind to set up eddies, or acquire an increased velocity, and so to reduce the amount of rain received in a horizontal gauge." These principles are clear enough, and they show the need for the adoption of a uniform height of gauge by all members of the rainfall organisation. At present it appears that not half the gauges in use are placed at exactly the standard height.

MESSRS. SWAN SONNENSCHEIN AND CO. have published a third and revised edition of "Land and Fresh-water Shells," by Mr. J. W. Williams, with a chapter on the distribution of the British land and fresh-water Mollusca, by Mr. J. W. Taylor and Mr. W. Denison Roebuck.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mr. G. Nicholson; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. J. McCarthy; a Short-toed Eagle (*Circaëtus gallicus*) from the Atlas Mountains, presented by Captain W. R. Taylor; a Passerine Parrot (*Psittacula passerina*) from South America, presented by Mr. W. C. Stronge; two Turtle Doves (*Turtur communis*), British, presented by Miss L. Cox; a Greek Tortoise (*Testudo graeca*) from South Europe, presented by Mr. Balfour Read; a Neumann's Baboon (*Cynocephalus neumanni*) from Central Africa, a Nisnas Monkey (*Cercopithecus pyrrhonotus*) from East Africa, a Striped Hyæna (*Hyaena striata*, var.) from North Africa, three Pale Fennec Foxes (*Canis pallidus*) from the Soudan; a Brazilian Caracara (*Polyborus brasiliensis*) from South America, a Black-headed Conure (*Conurus nanday*) from Paraguay, an Egyptian Monitor (*Varianus niloticus*) from North Africa, two Brazilian Tortoises (*Testudo tabulata*) from South America, two Sculptured Terrapins (*Clemmys insculpta*) from North America, three Muhlenberg's Terrapins (*Clemmys muhlenbergi*) from North America, a Pennsylvania Mud Terrapin (*Cinosternum pennsylvanicum*) from North America, three Laughing Kingfishers (*Dacelo gigantea*) from Australia, two White-capped Tanagers (*Stephanophorus leucocephalus*) from Argentina, three Striated Tanagers *Tanagra striata*) from Buenos Ayres, four Palm Tanagers (*Tanagra palmarium*) from South America, a King Snake (*Coronella getula*) from North America, two Ocellated Sand Skinks (*Chalcides ocellatus*) from North Africa, deposited; four Lesser Snow Geese (*Chen nivalis*) from North America, two Mute Swans (*Cygnus olor*), European, purchased; a Thar (*Hemitragus jemlaicus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SPECTRUM OF NOVA PERSEI.—A communication from Prof. Pickering to the *Astronomische Nachrichten* (Bd. 156, No. 3735) gives particulars of the examination of recent photographs of the spectrum of the Nova taken at the Harvard College Observatory. The reductions show that, as has been the case in previous Novæ, the object has been gradually changing into a gaseous nebula. The resemblance to the nebula N.G.C. 3918 was so close on June 20 that no marked difference in the two spectra was noticeable. The main point of divergence is in the relative intensity of the chief nebular line at λ5007, which in N.G.C. 3918 is about eight times as bright as $H\beta$, while in the Nova these two lines are about equal in intensity.

The following lines are common to both bodies:—

3869	4688
3970, $H\epsilon$	4862, $H\beta$
4102, $H\delta$	4959
4341, $H\gamma$	5007

and with the above-mentioned exception of λ5007 are of similar intensity. Four bright lines between $H\gamma$ and $H\beta$ appear faintly in the Nova, and are not present in the nebula, while one, at λ4364, is seen in the nebula, but not in the Nova, perhaps owing to the proximity of $H\gamma$.

NEW DOUBLE STARS.—*Bulletin* No. 3, from the Lick Observatory, contains a list of 94 new double stars discovered by Mr. R. G. Aitken, with the 12-inch and 36-inch telescopes, the majority of the measures being obtained with the larger instrument. The series has been compared with Prof. Burnham's Catalogue to ensure the absence of duplicate records of previous discoveries. Classified according to distance of their components the 94 pairs show the following grouping:—

Under 0″·25	... ...	3
0·50	... ...	23
1·00	... ...	47
2·00	... ...	73
Over 5·00	... ...	1

SIX STARS WITH VARIABLE RADIAL VELOCITY.—Prof. W. W. Campbell gives particulars in *Bulletin* No. 4 of the Lick Observatory of six additional spectroscopic binaries, of which variable velocity in the line of sight has been determined from spectra obtained with the Mills spectrograph of the Lick Observatory. The details of the measures are given below:—

Star.	Extreme velocities (kilometres).	
π Cephei	−37	−5
$o_1$31 Cygni	−12	+3
ξ Piscium	+25	+35
τ Persei	+10	−4
ξ_1 Ceti	−9	+4
ϵ Hydræ	+43	+32

CAUSES OF THE VARIABILITY OF EARTHSHINE.—In the May number of the U.S. *Monthly Weather Review*, Mr. H. H. Kimball gives an interesting discussion of the probable causes of the earthshine observed on the moon's shadow side some few days previous to, and following new moon. With the idea that the amount of light reflected from the earth to the moon will vary considerably according to the condition of the earth's surface and atmosphere, a special projection chart of the earth has been prepared, showing the configuration of the continents, oceans, &c., and general atmospheric conditions (clouds, &c.), on a certain evening when the earthshine was specially prominent. If the bright portion is snow-covered, it will reflect more than a continent of forest and vegetation, and much more than a large extent of water.

A factor of considerable importance is the varying distance of the moon, and it is stated that 52 per cent. of the change in intensity of the earthshine is due to the eccentricity of the moon's orbit, and this is probably much greater than could be expected from any increase or diminution in the average cloudiness over the hemisphere of the earth reflecting light to the moon.

SOLAR RADIATION.

SOLAR radiation is a subject which has more than scientific interest. It is the source of all the energy which maintains the economy of our globe. It lights and heats the other members of the planetary system. But, after accomplishing this, only an infinitesimal proportion of the total radiation has been used. The remainder, in so far as we know, is wasted by uninterrupted dissipation into space.

The subject can be regarded and studied from either the solar or the terrestrial point of view. In terrestrial physics everything may be said to depend on the energy which, in one form or another, is supplied by the sun's rays. It is the revenue of the world, and it is of fundamental importance for us to know at what rate it falls to be received.

Roughly speaking, the surface of the earth is occupied to the extent of one-fourth by land and three-fourths by sea. Therefore at least three-fourths of the surface which the earth presents to the sun is at the sea-level. Consequently the rate at which the sun's radiant heat arrives at the sea-level is the fact which it is of the greatest economical importance to ascertain.

In considering this problem we have to answer two questions: What is the best experimental method of determining the heating power of the sun's rays at any place? and What is the best locality for making the experiment? Let us take the last first. The energy which a radiation communicates to a surface is greatest when it strikes it perpendicularly. At every moment the sun is vertical over one spot or another of the earth's surface. Therefore our first step should be to choose a locality where the sun passes through the zenith at mid-day.

Before reaching the sea-level the sun's rays have to pass through the whole thickness of the atmosphere. It is a matter of every-day observation that the atmosphere varies in transparency. The second condition is therefore to put ourselves in the position of greatest advantage as regards atmospheric conditions. Clouds and similar visible obstructions are of course excluded. The air should be motionless, the sky should be clear and of a deep blue colour in the regions remote from the sun and should contain nothing that can be called haze, or that interferes with the definition of the sun or other heavenly bodies.

From inspection alone we can only approximately ascertain what are the most favourable meteorological conditions. For this reason it is necessary to multiply observations and never to miss fine weather. In the end we cannot fail to approach nearer and nearer to the exact determination of the maximum heating power of the sun on the earth's surface at or near the sea-level, in so far as the degree of perfection of our instrumental resources permits. This limitation imposes on us the duty to continue observations, not only until the best natural conditions have been found, but also so long as the instruments or experimental methods appear to be capable of improvement. If we suppose for one moment that we have arrived at the point where no further improvement is possible, then the result of our work is the determination of the rate at which unit area of the earth's surface at or near the sea-level receives heat from the vertical sun in unit time.

There is no question here of how much is lost on the way from the sun. All that is sought, and the most that is ascertained, is how much arrives. If we multiply this by the area included in the great circle of the earth we have the amount of radiant heat which we can count on as being supplied to the whole earth in unit of time. This is the constant which is of greatest importance in physical geography.

When we have ascertained the supply of radiant heat which reaches the earth's surface, we have to inquire what becomes of it. If the heat were to accumulate the world would become uninhabitable. It cannot be doubted that long ago the earth, in this respect, arrived at a condition of equilibrium which is maintained with very slight oscillations. The fundamental principle of this state of equilibrium is that the heat which the whole earth receives from the sun in the course of a year also leaves it in the course of a year, so that, taking one year with another, the sum of the heat remains the same.

When we study the details of the annual dissipation of heat we find that the atmosphere, and especially the aqueous vapour in it, performs a very important part. Although practically transparent to the heat-rays passing from the sun to the earth, it is very opaque to those leaving the earth to pass outwards. They are powerfully absorbed and the temperature of the atmosphere is thus raised considerably above that which it would have if it were as transparent to the leaving rays as it is to the entering ones. This has no effect in permanently detaining any of the year's supply, it still disappears in the year, but not before it has produced important climatic effects.

We see in this differential behaviour of the atmosphere towards the incoming and the outgoing rays an example of Kirchoff's law, in virtue of which a body absorbs by preference the rays which it itself emits. It is exceedingly unlikely that any portion of the rays coming directly from the sun proceed from highly heated water or water vapour; we should therefore not expect the water vapour in the atmosphere to absorb them to any appreciable extent. When, however, they strike the surface of the earth, whether it be land or sea, they are abundantly absorbed. The blue water of the ocean transmits the sun's visible rays to a considerable depth. In experiments made by the writer on board the *Challenger*, a white surface, about four inches square, was clearly visible at a depth of 25 fathoms. The total length of the path of the incident and reflected ray was 50 fathoms; therefore the sun's rays which strike the sea have a thickness of at least 100 metres to work on. When they strike the land, the direct effect is superficial, but the absorptive power of a surface of soil is very much greater than that of a surface of water, and it frequently attains a very high temperature. Even in the driest countries the soil is moist, and it may be that, ultimately, the surface of every particle of the soil is a water surface. Whether this be so or not, when a land surface cools, the heat of low refrangibility which it radiates proceeds to a very large extent from water, and it is accordingly abundantly absorbed by the water vapour in the lower layers of the atmosphere. In the absence of mechanical mixture by wind, these layers can lose it only by passing it on by radiation to higher layers which contain moisture, whence it ultimately escapes into space. This accumulating function of the atmosphere provides that while every portion of the earth's surface receives heat intermittently it loses it continuously.

As the heat of the atmosphere is due to contact with, or radiation from, the surface, it must be taken from the supply that reaches the surface of the earth. Further, wind and all mechanical atmospheric effects are due to differences of density, and these are produced, not only by the thermal expansion and accompanying rise of temperature of the air, but also, and without change of temperature, by the mixture with it of a lighter gas. Such a gas is the vapour of water, and the water which supplies it is at the level of the sea. Therefore the sun's heat which arrives at the surface of the earth at or near the sea-level has to maintain not only the temperature of the surface of the globe, it has also to maintain all the mechanical manifestations of the air and the ocean. This is the ground for asserting, as above, that the only constant which is of interest in terrestrial physics is the rate at which the vertical sun heats unit area of the earth's surface at the sea-level.

The instruments used for measuring the thermal effect of the sun's rays must fulfil certain conditions. The area of the sheaf or bundle of rays collected must be accurately known; and provision must be made for the exact measurement of the thermal effect produced by them in a given time. The thermal effect produced is measured by a mass of some substance and either by the change of temperature produced in it or by the change of its state of aggregation. Actinometers, such as those of Herschel, Pouillet, Violle, Crova, are instruments of the first kind. The ice calorimeter used by Exner and Röntgen and the steam calorimeter of the writer are instruments of the second kind. The thermal mass of the substance affected is conveniently expressed in terms of the thermally equivalent weight of water, which is called its water value. In the actinometer the change of temperature is either measured by a separate thermometer or the actinometer is itself a thermometer the calorimetric constants of which have been ascertained. In instruments of the second class no thermometer is required; the thermal effect is measured by the mass of water-substance which changes its state in a given time either from ice to water or from water to steam, both being at the same temperature. In the ice calorimeter the quantity of liquefaction is measured by the change of volume, as in Bunsen's calorimeter; in the steam calorimeter the generation of steam is measured by the weight or volume of the distilled water produced. The steam calorimeter was described recently in NATURE (vol. lxiii. p. 548), and it is unnecessary to repeat it here. It acted quite satisfactorily in the writer's hands in Egypt in May 1882, and it has since been giving good results in the hands of Mr. Michie Smith at the observatory of Kodaikanal in South India, at an elevation of about 7000 feet above the sea. Theoretically, the ice calorimeter is as good as the steam calorimeter, but in applying it to the measurement of the sun's radiant heat it has a practical defect. At the moment before exposure, the ice in the calorimeter is frozen to the inner surface of the metal plate, the outer surface of which receives the sun's rays. The first effect of exposure to the sun is that the ice is detached from the plate. The intervening water introduces perturbations which are not easily allowed for.

The fundamental principle of the actinometer is analogous to Newton's second law of motion; when a body is engaged in the exchange of heat between itself and any number of other bodies, each exchange takes place independently of the others. The rate of exchange in each case depends on the difference of temperature between the two bodies and takes place on the principle that equal fractions of heat are lost or gained in equal times. A body cooling in the air is always subject to at least two quite independent sources of loss of heat, namely, radiation between itself and the surrounding objects and conduction between itself and the contiguous air. In ordinary circumstances the rate of loss of heat by radiation is subject to but little variation, but that due to conduction is subject to continual variation owing to the varying rate at which the air actually in contact with the thermometer is renewed. It is not to be expected that a body subject to at least two independent sources of loss of heat will cool in the same way as it would if exposed to only one, any more than it is to be expected that a body acted on by two forces will move in the same way as if it were impelled by only one of them. The composition of rates of cooling is like that of velocities in the same straight line; the resultant rate is the net, or algebraic, sum of all the rates. When the actinometer is exposed to the sun, its temperature rises at first rapidly, and then more slowly until, if the experiment is sufficiently prolonged, it becomes stationary. The temperature is noted at equal intervals of time. The sun is screened off, either after the temperature has become stationary or beforehand, and the temperature is observed at equal intervals during cooling. Whenever the thermometer is at a higher temperature than its enclosure, it is cooling. Therefore when it is exposed to the sun's rays, and its temperature rises ever so little above that of the enclosure, cooling begins; and what is observed in the first operation is, not the rate of heating by the sun's rays, but that rate diminished by the rate at which the thermometer is cooling. Hence, when the two series of observations have been made and tabulated, the rate of rise of temperature when that of the thermometer is, say, 2°, 4° or 6° above that of the enclosure is found. Similarly, the rate of fall of temperature when the temperature of the thermometer is 2°, 4° or 6° above that of the enclosure during cooling is found. Three pairs of rates are thus obtained. The sums of all three pairs of rates should be alike, and each gives a value of the rate at which the temperature of the actinometer would rise when exposed to the sun if there were no cooling. The rule is the same whether the temperature is allowed to rise to the stationary point or not. A distinction is often made between the *static* method, when the experiment is continued until the stationary temperature is arrived at, and the *kinetic* method, when it is interrupted before that temperature is reached. This distinction rests on no substantial difference; at the same time it is convenient to retain the designations to distinguish the manipulative processes.

Were the protecting enclosures, such as the double spherical shell packed with melting ice, used by Violle, or the thick metal shell used by Crova, perfectly efficient, then it would not be necessary to make a separate cooling experiment in connection with every heating one. The necessity for it is due to the fact that, when the sun's rays are introduced, the temperature of the air in the enclosure no longer is, and it cannot be, at the temperature of the enclosing shell; nor can it remain motionless, as it is when at a constant temperature in the shade. These perturbations, which cannot be avoided, so long as there is air in the enclosure, make it impossible to apply a rate of cooling determined beforehand. It is necessary on each occasion to determine the actual integral rate of cooling during the particular experiment.

If the actinometer could be so arranged that the rate of cooling should not be affected by the introduction or exclusion of the sun's rays, the static method could be adopted without hesitation, and the instrument would become a valuable one for continuous self-recording observations. Their value would be mainly relative. The absolute value of the sun's heat radiation, as it reaches the surface of the earth, has to be determined by other means. When it has been ascertained in the most favourable circumstances it does not vary, excepting in the annual cycle of the earth's revolution. The diurnal variation, as shown by registering actinometers, would have a great local importance. Crova, in the long series of valuable observations which he has made since 1875 at Montpelier, has, in fact, put this principle in practice.

Very important observations have been made in the neighbourhood of Chamonix by Violle and afterwards by Vallot. The Annales de l'Observatoire météorologique du Mont Blanc contain, in vol. ii., several interesting reports on the results of these observations. They were made simultaneously at Chamonix and at certain stations on Mont Blanc. The first series of observations was made in 1887 on July 28, 29 and 30, and the instruments used were two "absolute actinometers" of Violle (*Ann. Chim. Phys.* (1879) [5], t. xvii.).

The great advantage of such experiments is that they are made simultaneously at two stations situated at very different altitudes. At the higher of the two the average barometric pressure is 430 millimetres, so that 33/76 of the whole atmosphere are below the observer, and this portion contains nearly all the aqueous vapour. Above him there is a little more than one-half, and that much the simpler and purer half of the atmosphere. In it aqueous vapour is almost absent. The summit of Mont Blanc is 4807 metres and the station at Chamonix is 1087 metres above the sea. The layer of the atmosphere separating them has, therefore, a thickness of 3720 metres, and it can be visited at any point in its thickness. M. Vallot has acquired a personal acquaintance with this layer of air which can only be obtained by devoting a number of years to living in it and observing it. It is this intimate and continuous acquaintance with so large a proportion of the earth's atmosphere that entitles the observations and conclusions of M. Vallot to especially great weight.

The main results of Vallot's observations are as follows. The ratio between the heat received in the same time by the same area exposed perpendicularly to the sun's rays on Mont Blanc and at Chamonix was found to be 0·82 to 0·85, which agreed well with the proportion found by Violle in 1875. The value of the solar radiation found was, however, much lower than that found by Violle. The maximum values observed by Vallot were 1·56 gr.° C. on Mont Blanc and 1·33 gr.° C. at Chamonix, whilst Violle found 2·39 gr.° C. on Mont Blanc and 2·02 gr.° C. at the Glacier des Bossons in the valley. Violle's observed values are therefore half as great again as Vallot's. No explanation of the cause of this discrepancy is offered, but it is pointed out that the values observed by Crova at Montpelier are more in accordance with Vallot's than with Violle's. They are interesting in themselves and are worth quoting. They relate to the year 1895, the summer of which was very hot.

Intensity of solar radiation observed by M. Crova at Montpelier in 1895, in gramme-degrees per square centimetre per minute:—

Season.	Means.				Absolute maxima.	
	Monthly.			Seasonal.		
Winter	1·02	1·12	1·15	1·09	1·32	January 28.
Spring	1·20	1·13	1·13	1·15	1·38	May 12.
Summer ...	1·22	1·14	1·19	1·18	1·42	July 24.
Autumn ...	1·30	1·20	1·02	1·17	1·41	September 8.

The subject was taken up again by Vallot in 1891, and this time he used the mercury actinometer of Crova (*Ann. Chim. Phys.* 1877 [5] xi., 461).

The result of the experiments in 1891 was in the main confirmatory of those obtained in 1887. In the following table the intensities of solar radiation on September 19, 1891, are given as observed on Mont Blanc and at Chamonix:—

	Hour.	9 a.m.	10.	11.	Noon.	1 p.m.	2.	3.
Observed Radiation.	On Mont Blanc	1·34	1·30	1·36	1·38	1·34	1·33	1·31
	At Chamonix	1·11	1·16	1·19	1·15	1·16	1·09	1·01
Ratio of intensities.		0·83	0·89	0·87	0·83	0·87	0·82	0·77

The mean value of the ratio of the intensities is 0·84, as before. The values of the intensity of radiation are rather lower than those found in 1887.

In the year 1896 Prof. Ångström, of Upsala, made observations on the peak of Tenerife with a special form of actinometer depending on the heating of metal plates. He made observations at three different elevations, namely, at Guimar, 360 metres, Cañada, 2125 metres, and at the summit, 3683 metres. Reduced to a uniform thickness of one atmosphere corresponding to a pressure of 760 mm., the intensity of radiation by the vertical sun was found to be at Guimar 1·39, at Cañada 1·51, and at the summit 1·54 gramme-degrees per square centimetre per minute. These values agree more closely with the values found in 1887 by Vallot than with those of 1891. But the values found by Crova, Vallot and Ångström are all of the same order.

The writer's observations with the steam calorimeter in Egypt in May 1882 were undertaken with the object of ascertaining the maximum rate of distillation near the sea-level under the most favourable circumstances. This occurred during the forenoon of May 18, when the meteorological conditions were as favourable as they could be. The sun shone steadily in a cloudless sky, and the air was motionless. The shade temperature reached 40°·5 C. in the course of the day. Time was taken as portions of 5 cubic centimetres were distilled. The shortest time in which this quantity passed was 3m. 20s. This is at the rate of 1·5 c.c. per minute, and it occurred twice in the forenoon, namely, at 10h. 37m. and at 11h. 23m. As the collecting area of the reflector was 904 square centimetres, this corresponds to 16·6 c.c. distilled per minute per square metre. If we apply a correction for 20° zenith distance it becomes 17·04 c.c. The evaporation of 17·04 grammes of water at 100° C. requires 9116 gr.° C. of heat, so that the heat actually collected and used in making steam was at the rate of 9116 gr.° C. per square metre or 0·9116 gr.° C. per square centimetre per minute. Converting 9116 gr.° C. into work at the rate of 0·425 kilogramme-metres per gramme-degree, we obtain as the realised working value 3875 kilogramme-metres per minute or 0·87 horse-power per square metre. The reflector consists of one mirror inclined at an angle of 45° to the axis of the instrument. This mirror throws all the reflected rays normally on the surface of the axial boiler. The larger mirror outside and the smaller mirror inside of this one throw their reflected rays inclined at small angles to the normal. Taking all the reflected rays together their mean normal component is 94 per cent. of the total reflected rays. It is therefore legitimate to increase the above figures in the proportion of 94 : 100, giving 0·93 horse-power or 9700 gr.° C. per square metre per minute. The mirrors are not perfectly reflecting, nor is the blackened surface of the boiler perfectly absorbing. An allowance of 7 per cent. for these deficiencies will not be thought extravagant, and we have in round numbers the work-value of the sun's vertical rays on the surface of the earth at or near the sea-level as 1 horse-power per square metre; the equivalent of this in heat is 10,300 gr.° C. per square metre per minute, or 1·03 gr.° C. taking the square centimetre as unit of area.

Mr. Michie Smith informs the writer that the highest rate which he has observed is 1·754 c.c. distilled per minute at a height of 7000 feet above the sea. This is exactly seven-sixths of the maximum rate observed on the banks of the Nile. If we imagine that in the most favourable circumstances the radiation as determined in Egypt might be improved in this proportion we get 1·17 horse-power per square metre and 1·202 gr.° C. per square centimetre per minute as a value of the heating power of the sun at the sea-level, which is probably very near the truth.

Comparing these results with those already quoted, we see that they agree with Crova's summer values as determined at Montpelier and lie midway between Vallot's (1891) values for Mont Blanc and Chamonix. We arrive therefore at the conclusion that the rate at which the surface of the earth at the level of the sea receives heat in the most favourable circumstances from the vertical sun is 1·2 gr.° C. per square centimetre per minute, or 1·17 horse-power per square metre. In discussing questions of terrestrial physics it would not be prudent to postulate a more abundant supply.

If we ascribe to the atmosphere a coefficient of transmission no greater than two-thirds, the value of the *solar constant*, or the heating power which the sun's rays would exert on a surface of one square centimetre exposed to them for one minute at a point on the earth's orbit, is 1·8 gr.° C. As the transmission coefficient is probably greater than two-thirds, the value of the solar constant is probably less than 1·8. Vallot, by giving effect to the rate of absorption actually observed in the air separating his two stations, arrives at 1·7 gr.° C. as the most probable value. These values are in substantial agreement with the older ones, such as those of Herschel and Pouillet; but there is a feeling at present that not much weight is to be attached to these results, and much higher figures seem to be more readily accepted. In a recent work, "Strahlung und Temperatur der Sonne," p. 38, J. Scheiner sums up the discussion of this subject by giving 4 as the most probable value of the solar constant.

As we have seen, the heat which arrives at the sea-level has to support the temperature of the land and that of the sea; it has also to supply the energy for all the movements of the ocean; it has to warm and expand the air, and to furnish the latent heat represented by the aqueous vapour in the atmosphere, and it is mainly accountable for winds and storms. All this is maintained on less than 1·5 gr.° C. per square centimetre per minute. But when the above catalogue of functions has been repeated, there is nothing left to be accounted for. If the sun's rays enter at the top of the atmosphere with an intensity of 4 and come out at the bottom of it with an intensity of only 1·5, how is the loss to be accounted for? It represents nearly double the energy which reaches the sea-level and produces such far-reaching effects. If it really entered the atmosphere it must be still there, either as heat or as its equivalent. But we know that the air is not made appreciably warmer by it, and we see no mechanical manifestations which can in any way be put forward as an equivalent. We conclude therefore that there is no excess of heat of this order to be accounted for, consequently values of the solar constant of the order of 4 are exaggerated.

J. Y. BUCHANAN.

REFLEX ACTION AND INSTINCT.[1]

IN the Paris *Journal of Anatomy and Physiology* of 1869 there was reported by Robin an experiment on the body of a criminal whose head had been removed an hour previously, at the level of the fourth cervical vertebra. The skin around the nipple was scratched with the point of a scalpel. Immediately there ensued a series of rapid movements in the upper extremity which had been extended on the table. The hand was brought across the chest to the pit of the stomach, simultaneously with the semiflexion of the fore-arm and inward rotation of the arm, a movement of defence as it were.

Probably none of us have seen quite so impressive an illustration of reflex action as the above, but most of us have watched the experiment in which a frog, having been decapitated and a drop of acid having been applied to its skin, the foot of the same side is brought up to wipe away the acid, and if this foot be cut off, after some ineffectual efforts and a short period of hesitation, the same action will be performed by the foot on the opposite side. These symptoms of apparently purposive action on the part of a brainless body have always struck me as most strange.

Some four years ago I had the privilege of reading to you a paper on memory, from which I will now quote:—"When we attempt to acquire some new feat of manual dexterity, involving a series of combined muscular movements, such as a conjuring trick, we find that, when first attempted, each movement has to be thought out, and the whole is effected with difficulty. Every time that the process is repeated the action becomes more easy; each movement of the muscles involved follows its predecessor with greater readiness, and at last the trick becomes apparently one action, is performed without thought, and may be said to be automatic. The nerve structures involved have acquired a perfect memory of what is required of them; each takes up its part at the proper moment, and hands on in succession an intimation to its neighbour that it is time to transmit the expected impulse. Nerve centres have been educated. An organic memory has been established."

I went on to give instances in which, by frequent practice, actions had become so habitual as to take place on the application of the stimulus without the will of the individual, and even contrary to his wish. I gave as an illustration the story of the old soldier who was carrying a pie down the street, when some one mischievously crying "Attention!" down went the soldier's hands to his trousers seams, and down went his dinner in the mud.

Let us apply this effect of constant practice to the case in question. The frog has a smooth, soft skin, unprotected by hair or scales. His haunts are stagnant water which swarms with injurious insects and other enemies; or the banks of ponds and streams abounding in sticks and stubs. From the time when the first progressive tadpole protruded his incipient legs, the race of frogs has been brushing away irritating substances. The nerve cells of their spinal cords have established such relations that, whenever a sense of irritation is conveyed to sensory cells, motor cells in connection are brought into action, and a complicated muscular movement follows, without the necessity of the interference of the will.

We may compare the association of nerve cells in the spinal cord to a group of men highly drilled in particular evolutions. Each individual cell of the group maintains relations with others near it by some one or more of its many arms. Upon the receipt of the intimation through sensory nerves and cells that there is something burning a particular portion o the frog's skin, motor

[1] A paper read before the Derby Medical Soc ety b W. Benthall, M.B., on April 9, 1901

cells accustomed to act with these sensory cells send out messages to particular muscles. If the message is responded to, if the foot comes up and the offending particle is brushed away, the stimulus and the effort cease. If the stimulus still goes on, other cells which supply accessory muscles are called into play. If this effort to remove the offending matter is vain, and the irritation still goes on, the stimulus is passed on to other cells, which have in an emergency previously been in the habit of assisting; the stimulus thus travels to the opposite side of the spinal cord, and the other leg now comes up to the point required.

It is the effect of drill, of practice, in the forgotten past. I am aware that in making this statement I am assuming the inheritance of acquired powers—an assumption directly in opposition to the views of Weismann, who maintains that no powers acquired during the lifetime of the individual are transmitted to the progeny.

The development of the reflexes and instincts which we shall refer to will be seen to be of such importance to the maintenance of the life of the individual or to the procreation of its race; that the slow and gradual formation of nervous connections can probably be explained by the Weismann theory; but for our purposes to-night the assumption of the inheritance of acquired powers enormously increases the ease with which we can understand their development.

The idea of this paper is therefore that, as in the *individual*, constant habit causes in time such a free connection between nerve cells as to facilitate the passage from cell to cell of a particular stimulus until the action follows the stimulus automatically, so in the *race* a particular response to a particular stimulus has been repeated so often that the connection has become congenitally perfect, has become in fact what we know as a reflex. And, further, that the frequent repetition of particular actions under similar stimuli have so influenced the *intelligent* actions of the animal, that *they* also have become engrafted upon the nerve system, and recur under the influence of similar stimuli in an automatic manner; the result of these reactions of the intelligence to a particular stimulus being what we know as instincts.

The great advantage of a reflex is the certainty and usually the rapidity with which it acts. The response to the stimulus does not have to travel round through the brain. It takes a short cut. With imperfect reflexes the animal is at the mercy of its surroundings.

Nature does not pass imperfect work. The eye reflexes, for instance, have been developed by constant practice. If through their failure an animal were partially blinded, some self-constituted Factory Inspector in Nature's workshop would soon get on the blind side of that animal, and there would be no chance of its perpetuating its failings. If the cough reflex failed, some septic fly would quickly start a fatal pneumonia.

Assuming that all reflexes have been developed by practice, it follows that our own are not merely aids to the diagnosis of disease at the hands of the physician, but are now, or have been, of use in some period of our history.

A year or two ago, in the *British Medical Journal*, there was a very interesting description of the strength of the reflex grip of the newly-born infant, this being sufficient to maintain the weight of the child for some minutes while hanging from a stick. This the writer attributed to the necessities of a time before perambulators, when a child had to hang on for bare life to its mother's hair or clothes. The inward-turned feet of the newly-born child and the plantar reflex point to a time when the feet were used for climbing and for grasping.

Many of the superficial reflexes were probably developed to get rid of flies and other irritants which must constantly have troubled the naked body. The reflex action exhibited by the decapitated body, described at the commencement of this paper, was attributed by the observer to an attempt at self-defence. I think it was more probably an attempt at scratching, an act which was probably habitual in our hairy ancestors, as it is now in our poor relations at the Zoo—a movement, in fact, strictly analogous to the movement of the frog's foot incited by the irritation of the acid. To assume that there was an intention of defence in the action imports into the movement an element of consciousness for which in the absence of the brain we have no warrant; and this brings us to the question of instincts, which have been defined as reflex actions into which an element of consciousness has been imported.

I will endeavour to trace an ascending scale of instincts showing their dependence on reflex excitation. A newly-born infant has to be placed to the breast; it then seizes the nipple with its lips and sucks. There is little difference between the reflex action incited by the contact of the maternal nipple with the infant's mouth and the cough or sneeze reflex; both are complicated actions of many groups of muscles. In the one case, spasmodic; in the other, rhythmical. The young of the rabbit, born blind and helpless, nuzzles about till it finds a nipple, and then takes its hold. The lamb, calf, or fawn, guided by sight and smell, *seeks* its mother's teat. In each of these cases a stimulus is required, either of touch, sight, or smell. Without the stimulus the experiment fails.

Fawns are peculiarly precocious. From the first they show a tendency to couch and hide on the approach of danger. The following is an extraordinary instance of combination of maternal and infant instinct:—

"I have had frequent opportunities," says the "Naturalist in La Plata," "of observing the young from one to three days old of the *Cervus campestris*, the common deer of the Pampas, and the perfection of its instincts at that tender age seems very wonderful in a ruminant. When the doe with fawn is approached by a horseman, even when accompanied by dogs, she stands perfectly motionless, gazing fixedly at the enemy, the fawn motionless by her side; and suddenly, as if at a preconcerted signal, the fawn rushes away from her at its utmost speed, and going to a distance of 600 to 1000 yards, conceals itself in a hollow in the ground or among the long grass, lying down very close with neck stretched out horizontally, and will thus remain until sought by the dam. When very young it will allow itself to be taken, making no further effort to escape. After the fawn has run away, the doe still maintains her statuesque attitude, as if to await the onset; and when, and only when, the dogs are close upon her, she also rushes away, but invariably in a direction as nearly opposite to the fawn as possible. At first she runs slowly with a limping gait, and frequently pausing as if to entice her enemy on, like a partridge, duck, or plover when driven from its young; but as the dogs begin to press her more closely her speed increases, becoming greater the further she succeeds in leading them from the starting point."

In considering this case we have to remember that the deer is, as a rule, a woodland animal, and that its fawn, while feeble, crouches under cover, of which there is plenty within immediate reach; but the deer of the Pampas lives on rolling prairies where the only cover is the isolated tufts of Pampas grass. While, therefore, the instinct to crouch is sufficient for the fawns of most deer, crouching in the immediate neighbourhood of the surprise would be useless in the open ground of the Pampas; and this artful combination of tactics has doubtless been developed by practice.

In birds we get even more marked differences in connate powers and instincts, from the naked young of the sparrow, which is nearly as helpless as the human baby, to the newly-hatched chicken, which is a regular little man-about-town at once. The habits of the latter have been closely studied. Hatched out in an incubator, and deprived of all maternal instruction and example, he quickly begins to peck at all small objects, with a preference for moving ones, and from the first shows an almost perfect power of estimating distance and direction, which is very marvellous when we consider the great number of muscles which have to be co-ordinated in the act.

The late Mr. Douglas Spalding placed beyond question the view that all the supposed examples of instincts may be nothing more than cases of rapid learning, imitation, or instruction, but also proved that a young bird comes into the world with an amount and a nicety of ancestral knowledge that is highly astonishing. Thus speaking of chickens which he liberated from the egg and hooded before their eyes had been able to perform any act of vision, he says that on removing the hood, after a period varying from one to three days, "almost invariably they seemed a little stunned by the light, remained motionless for several minutes, and continued for some time less active than before they were unhooded. Their behaviour was, however, in every case conclusive against the theory that the perceptions of distance and direction by the eye are the result of experience or of associations formed in the history of each individual life. Often, at the end of two minutes, they followed with their eyes the movements of crawling insects, turning their heads with all the precision of an old fowl. In from two to fifteen minutes they pecked at some speck or insect, showing not merely an instinctive perception of distance, but an original ability to judge and to measure distance with something like infallible accuracy. A chicken was unhooded when nearly three days old. For six minutes it sat chirping and looking about it; at the end of that time it followed with its head and eyes the movements of a fly twelve inches distant, at twelve minutes it made a peck at its own toes, and the next instant it made a vigorous dart at the fly, which had come within reach of its neck, and seized and swallowed it at the first stroke; for seven minutes more it sat calling and looking about it. For about thirty minutes more it sat on the spot where its eyes had been unveiled without attempting to walk a step. It was then placed on rough ground within sight and call of a hen with a brood of about its own age. After standing chirping for about a minute, it started off towards the hen, displaying as keen a perception of the qualities of the outer world as it was ever likely to possess in after life. It never required to knock its head against a stone to discover that there was no road there. It leaped over the smaller obstacles that lay in its path and ran round the larger, reaching the mother in as straight a line as the nature of the ground would permit. This, let it be remembered, was the first time it had ever walked by sight."

In this experiment each movement of the chicken appears to have been started by an external stimulus. It pecked at the flies which it saw. It jumped or evaded the objects which it saw in its path. It remained stationary until its hereditary tendencies were stimulated by the sound and sight of the old hen in its neighbourhood.

Mr. Spalding again says:—"The art of scraping in search of food, which, if anything, might be acquired by imitation, is nevertheless another indubitable instinct. Without any opportunities of imitation, when kept quite isolated from their kind, chickens began to scrape when from two to six days old. Generally the condition of the ground was suggestive, but I have several times seen the first attempt, which consisted of a sort of nervous dance, made on a smooth table." Mr. Spalding, however, does not seem to have seen them scrape unless the ground was suggestive, and Dr. Allen Thompson hatched out some chickens on a carpet where he kept them for several days. They showed no inclination to scrape because the stimulus applied to their feet was of too novel a character to call into action their hereditary instinct; but when Dr. Thompson sprinkled a little gravel on the carpet and so supplied the appropriate or customary stimulus, the chickens immediately began their scraping movements. Here, again, we see the hereditary instinct requiring a local stimulus to bring it about.

Mr. Spalding again says:—"A young turkey, which I had adopted when chirping within the uncracked shell, was on the morning of the tenth day of its life eating a comfortable breakfast from my hand, when the young hawk in a cupboard ust behind us gave a shrill chip, chip, chip. Like an arrow the poor turkey shot to the other side of the room, stood there motionless and dumb with fear, until the hawk gave a second cry, when it darted out at the open door right to the extreme end of the passage, and there, silent and crouched in a corner, remained for ten minutes. Several times during the course of that day it again heard these alarming sounds, and in every instance with similar manifestations of fear." Generations of young turkeys must in their native home have had cause to dread the cry of birds of prey; and the hereditary lesson had been well learned.

A water-bird was reared from the egg by another observer. It would swim freely, but he could not get it to dive by any means which he tried. One day while watching it in the water, a dog suddenly appeared on the bank. The necessary stimulus was applied; the hereditary reflex was set in action, and in the twinkling of an eye the bird had dived.

Handed down from generation to generation as these instincts have been, and impressed upon their owners by the imperative law that failure to inherit an instinct or a reflex meant death to the degenerate, these reactions persist long after they have failed to be of use.

As Dr. Louis Robinson has pointed out, the horse roamed, in a wild state, over plains of more or less long grass and low bushes. When a horse is alarmed, he throws up his head to get as wide a view as possible. The cow on the other hand keeps her head low, as if to peer under the boughs which covered the marshy grass of her jungle home. The horse's chief danger lay when, as he approached a stream to drink, he was liable to be sprung upon by a lurking lion; and to this day the two things that a horse dreads most are the rustling in bushes or reeds by the road-side and the wheelbarrow or tree-stump which his imagination depicts as a crouching enemy.

The dog once formed his lair in rough stuff, and now, when approaching sleep gives the accustomed stimulus, our pet dogs turn round three times upon the hearthrug to smooth down imaginary grass stubs. As an instance of an instinct which by its persistence under altered circumstances has become actually prejudicial, I may give the case of some shore-birds which had for many years nested upon flats covered with pebbles. As long as the pebbles remained, the eggs, which closely resembled them in markings, were rendered inconspicuous, but as the sea receded and grass grew, the pebbles became few and far between. The birds still, however, kept to their haunt, and actually collected pebbles around their eggs, thereby rendering their nests the more conspicuous.

In domestic fowls the habit of cackling as soon as they have laid an egg would certainly be detrimental to a wild race, and Hudson makes some interesting remarks on the modified habit in a semiferal race. The Creolla fowls, descended through three hundred years from the fowls introduced by the early settlers in La Plata, are much persecuted by foxes, skunks, &c., ever on the look-out for their eggs or themselves. These fowls in summer always lived in small parties, each party composed of one cock and as many hens as he could collect—usually three or four. Each family occupied its own feeding-ground, where it would pass a greater portion of each day. The hen would nest at a considerable distance from the feeding-ground, sometimes as far as four or five hundred yards away.

After laying an egg she would quit the nest, not walking from it as other fowls do, but flying, the flight extending to a distance of from fifteen to about fifty yards; after which, still keeping silence, she would walk or run, until, arrived at the feeding-ground, she would begin to cackle. At once the cock, if within hearing, would utter a responsive cackle, whereupon she would run to him and cackle no more. Frequently the cackling call-note would not be uttered more than two or three times, sometimes only once, and in a much lower tone than in fowls of other breeds. If we may assume that these fowls in their long semi-independent existence in La Plata have reverted to the original instincts of the wild *Gallus bankiva*, we can see how advantageous the cackling instinct must be in enabling the hen in dense tropical jungles to rejoin the flock after laying an egg, while if there are egg-eating animals in the jungle intelligent enough to discover the meaning of such a short subdued cackle, they would still be unable to find the nest by going back on the bird's scent, since she flies from the nest in the first place! It is obvious that while this form of cackling is useful, excessive cackling would in a state of nature lead to its own suppression.

We may suppose that as the wild fowl became more and more closely domesticated the eggs of the greater cacklers were more rapidly found and preserved by their mistresses, and this tended to increase the tendency to cackle; while in the half-wild fowls of settlers who had plenty to do besides looking after their poultry, there was a gradual reversion to the wild type by the elimination of the eggs of loud cacklers when not rapidly retrieved.

Birds which nest within a short distance of the ground display, as a rule, great skill in concealing their nests, and are very conservative in type. How is it that one chaffinch's nest is so like another's?

Gregarious birds like rooks have opportunities for learning by imitation, and may thus have lost some of their spontaneous skill. I have read somewhere that, when rooks were introduced into the Antipodes, young birds having been selected for transportation, they were found, when the breeding season came round, to be at fault, and finally imitated the nest of some native bird; but chaffinches build apart from one another; how, then, do they get their nests so nearly alike? A great observer has suggested that this is due to recollection on the part of the nesting pair of the home in which they were reared. This explanation does not commend itself to my mind, and is refuted, if not by the instance of the rooks just quoted, by the fact that tame canaries hatched in a nest of felt will, when they themselves breed, use moss for the foundation of their nest, and hair as a lining, just as a wild bird would do, although, as they build in a box, the hair alone would be sufficient.

If you want examples of what pure instinct can do, go to the insect world. There you get them in infinite variety. Hatched from the egg long after the death of the mother, the majority of insects have to depend entirely on the duly ordered reaction of their nervous organisms to stimuli similar to those which have for ages incited their forerunners.

The bot of horses has been hatched from the egg inside the stomach of its host. After some nine months' residence in the intestines, it is passed with the fæces and subsequently becomes the bot-fly. Until it becomes a perfect insect it has never seen the outside of a horse, and yet, as soon as it sees one, it knows exactly where to deposit its eggs in a position from which they can be licked off and swallowed in their turn. The sight and perhaps the smell of the horse is sufficient to inspire the hereditary desire to deposit eggs in a particular spot. If the stimulus and its reaction were insufficient, that particular bot-fly would cease to propagate.

The garden spider, again, hatched from an egg laid the previous autumn, brings an enormous amount of hereditary skill into the vicissitudes of its life. It selects its site, builds its web, adapts it according to the most approved plans to fortuitous circumstances, and distinguishes between harmless flies and dangerous wasps with an innate cunning which is an exact replica of the actions of the last year's brood. The nest of the trapdoor spider, too, is quite as wonderful a production as the nest of any bird.

Caterpillars, when they have reached their full growth, display great skill in selecting appropriate hiding places in which to pass into the chrysalis form, and those which weave cocoons do so in recognised stages. Huber has described one which makes, by a succession of processes, a very complicated hammock for its metamorphosis; and he found that if he took a caterpillar which had completed its hammock up to say the sixth stage of construction, and put it into a hammock completed only to the third stage, the caterpillar did not seem puzzled, but completed the fourth, fifth, and sixth stages of construction. If, however, a caterpillar were taken out of a hammock made up, for instance, to the third stage, and put into one finished up to the ninth stage, so that much of its work was done for it, far from feeling the benefit of this, it was much embarrassed, and forced even to go over the already finished work, starting from the third stage which it had left off at, before it could complete its hammock. In this experiment it would appear that each instinctive action calls other actions in definite order, and unless the proper sequence is maintained the intelligence of the insect is unequal to bridging the gap.

Now let us apply the facts and inferences aforesaid to the nesting of the chaffinch. We have seen how habits acquired during the life-time of the individual impress themselves upon the nervous connections, until, when the accustomed stimulus is applied, they become quite independent of the will. We have seen how certain reflex phenomena which are necessary for the life of the individual have, through congenital connections, become so automatic, that they take place whether the brain is present or not. We have seen how habits of wild animals have, through similar nervous bonds, been handed down to tame descendants long after the said habits were useless and even detrimental. We have noted that ancestral habits may lie in abeyance until some perhaps unexpected stimulus arouses them—for instance, the scraping of chickens when placed upon gravel, or the diving of a water-bird upon sudden fright. We have ascertained that many of these instincts are certainly not due to instruction by older animals, but are purely spontaneous; that in insects these spontaneous actions are often most complicated, and are sometimes *not only* carried out in definite order, as in the weaving of their cocoons, but *cannot* be carried out except in that definite order.

The inference I draw is that the nest-building of the chaffinch is due to a succession of reflexes. You remember that when Alice was wandering about in Wonderland, she was continually coming upon medicine-bottles, marked "Drink me," or upon pieces of cake, marked "Eat me." You remember that when Alice obeyed these directions strange things happened. Alice was able to decipher her labels by the result of long and painful study in her nursery. Had they been written in the Cuneiform character, though perhaps perfectly intelligible to another, they would have conveyed nothing to her. The nervous system of the chaffinch has been educated by generations of hereditary experiences, and when the newly-wedded chaffinch pair start upon their housekeeping, they see in their mind's eye, upon some suitable site, a label marked "Build here"; they go through the stages of their architecture much as the caterpillar spins the different stages of its cocoon, each stage suggesting its successor; and each twig, hair, or feather which they use, bears upon it a label, "Use me next."

THE EDUCATION OF ENGINEERS.

SEVERAL papers on the training of engineers have recently come under our notice, and it seems worth while to bring together some of the expressions of views upon this important subject. It is difficult, if not impossible, to lay down any hard and fast line as to the course to be adopted by a youth who wishes to become a qualified engineer, for the way to follow must depend largely upon the position, age, prepotency and previous training of the aspirant. Assuming, however, that the principles of science have been studied at school, with practice in the physical laboratory, the question is, what is the next step to be taken? The answers to this are many and various, as will be gathered from the following notes from recent papers on the subject.

A paper on the training of electrical engineers, read by Dr. J. T. Nicolson before the Manchester section of the Institution of Electrical Engineers and published in the *Journal* of the Institution (May 1901, No. 150), with the discussion upon it, contains some noteworthy statements. The province of the laboratory in the scheme of electrical engineering is, Dr. Nicolson remarks, first to extend scientific knowledge by providing more experimental data; secondly, to show the student the scope, value and limitations of the theories he has studied in the class-room; and thirdly, to provide object-lessons on the general trend of electrical engineering design by means of machines and instruments of the newest types procurable.

Theory must not, however, be neglected. "Resting on a strong foundation of mathematics, physics and chemistry, the knowledge of the engineer must always include such pure sciences as those of kinematics, dynamics, hydrodynamics, thermodynamics and electrodynamics. A sound elementary acquaintance with all of these is necessary, and a specialised knowledge of that one more particularly useful to the engineer in his own branch must be obtained. It is, for instance, quite hopeless to try to explain to a man who has no knowledge of dynamics, upon what principles one proceeds in endeavouring to balance a locomotive. No amount of laboratory experiment will enable him to dispense with a knowledge of the mechanical principles involved. Again, the fundamental principles of thermodynamics may not be of much use in helping a man to fix the size of the cylinders of a steam engine; but they will, at all events, keep him from wasting his time in trying to design a perpetual-motion machine, and they will show him how far he can hope to go in the direction of the improvement of his heat motors, or other energy transformers." As Prof. Perry has said:—"An electrical engineer must have such a good mental grasp of the general scientific principles underlying his work that he is able to improve existing things and ways of using these things."

This latter qualification, a knowledge of theory, he must acquire by private study and from his college lectures; the former will be best inculcated by experimental work in the laboratory. In the electrical profession, considerable difference of opinion exists concerning the stage at which a youth should enter the works, if he is free to choose. Dr. Nicolson holds strongly the opinion that, after leaving school, the boy who intends to become an electrical engineer should first spend at least two years in the workshops of a *mechanical engineer.* Here he will learn the elements of smithing, moulding, pattern-making, fitting, machine-work and erecting. In this time he cannot help picking up the names and appearance of the common implements and processes fundamental to all kinds of engineering practice. Having put in two years in a mechanical engineering workshop, Dr. Nicolson thinks the student ought to enter an engineering college at about the age of eighteen, and he ought to study there for not less than three years.

"This last portion of his laboratory time should be devoted by our embryo electrical engineer to what is, in America, called 'thesis' work. This is of the nature of an experimental research, carried out either by the student himself or by a small group of students of which he is one. Very much valuable information has been obtained in American colleges in this way, regarding the various types of new apparatus continually coming out; and it is found that the students learn, in the course of such work, to assume responsibility by being in a large measure left to their resources. Such investigation usually requires either special apparatus or the loan of new types of machinery; but good work may also be got by making progressive tests of an operating plant either in the college or elsewhere."

In the discussion upon Dr. Nicolson's paper, the view that an interval between school and college should be passed in an engineering works was not generally accepted. In the opinion of most speakers, it is better for a youth to go straight from school to a technical college for three years, and to obtain workshop experience after the college training, than to enter works at once. Dr. E. Hopkinson pointed out that for a boy to leave school at about the age of sixteen, and to enter a workshop with the idea of returning to school or college after an interval of two or three years involves a break in the scholastic course, and in habits of learning, which often has disastrous results. The best men are usually those who have had a continuous school and college career up to twenty-two or twenty-three years of age.

Another plan proposed is a combination of the half factory and half technical school, and this system is now under the consideration of the Manchester Association of Engineers. Mr. M. P. Higgins advocates the establishment of schools of this kind in an article in the August number of *Feilden's Magazine*. Such a school should, he says, possess the following features:—(1) a first-class commercially successful and productive machine-shop, which is a department coordinate in importance, influence and educational value with the academic department; (2) the pupils to be given instruction and practice in this shop during half the working hours in five days of each week, for a period of four years; (3) instruction in the public schools to be given during a portion of the other half of the time, equivalent to a high-school course, restricted, abridged and improved to meet the needs of these pupils; (4) special care and method of selection of pupils who have finished the grammar-school course and who have special aptitude for mechanical work; (5) management under a corporation whose trustees shall be practical business men.

If technical colleges were equipped with ordinary commercial apparatus and machines and kept in complete touch with engineering advances, much of the difficulty as to training would be removed, for students at such colleges would be able to combine the realities of the workshop with the theoretical instruction. But, as Dr. Nicolson pointed out in his paper, the data available in an engineering school are seldom of the latest, unless the teacher spends his summer in obtaining them. The instructor in electrical engineering has the special difficulty of the newness and constant development of his subject to contend with; but if he follows the practice of every year visiting the plants of the manufacturing companies and typical light and power stations, information is obtained which cannot be found in engineering literature and which has the highest value for educational purposes. The cultivation of close relations between the college and the practising profession should, indeed, be part of the duty of instructors and ought to be eagerly reciprocated by the working engineers as one of the surest ways of meeting foreign competition.

The closer sympathy between science and industry is, indeed, probably the most important factor to be considered. Engineers should see that technical colleges are brought into contact with current work, and arrangements might be made whereby young men from works could be sent from works to the laboratories of scientific institutions to carry on researches for the benefit of the firms employing them. This system is already partly in vogue in Germany and America, and has produced very gratifying results.

This summary of opinion may appropriately be concluded with some extracts from an article on the engineer of the twentieth century, by Prof. V. C. Alderson, Dean of the Armour Institute of Technology, Chicago.

"In the realm of mathematics the training of the engineer will be most rigid and exact. He will cut loose from the idealistic, academic mathematics, as the student of higher literature will cut loose from mere grammars. His mathematics must run down through his fingers, as it were. Mere juggling with symbols will be useless to him. He must regard his mathematics as one of his tools, as a means to an end, or as a language in which to express his thoughts. The future engineer may be successful if his training has included a greater or less amount of shop practice with perhaps indifferent laboratory instruction and a meagre equipment, but no engineer can be broadly successful and thoroughly competent without a deep and exhaustive theoretical treatment of engineering subjects. This does away with the common opinion that literature and books are not essential to the engineer's success, for the next quarter of a century will see the engineering profession rise to the dignity of the older professions.

"The conditions which will beset the engineer of the twentieth century will be exacting beyond anything we now know. The importance of a strong foundation in scientific principles cannot be over-estimated, for scientific principles are only the laws of nature. These principles cannot be learned readily after a man has begun his life work. His whole energy will then be devoted to applying these principles correctly, not in acquiring them laboriously. It will be a prime necessity for the technical college of the future to lay these foundations broad and deep. It will be regarded as a weakness for a college to teach its students only the knacks of the profession, only just enough to be an ordinary draughtsman, a tolerable surveyor, or first-class linesman.

"The technical graduate of the twentieth century will be marked by certain characteristics which are too rarely found in men trained in the colleges of literature and arts. Among these are directness of purpose, intellectual accuracy and clear thinking. The student of science and technology is trained in the realm of realities, where to commit error, to act without purpose, or to think vaguely are seen at once to be fruitful of harm. Economic and industrial needs will bring education from the cloistered lecture-room into the open air of the laboratory. Technical education will have a practical, helpful bearing upon the problems of life. No longer will the seclusion of the scholar be a mark of honour. Education will be found at the bench, by the forge, in the shop, the laboratory and the drafting-room, as well as in the library. The lesson to be taught will be how to apply scientific ideas to the solution of problems actually arising in the struggle to bring the forces of nature under the sway of man.

"As technical education develops, questions of far-reaching importance must be settled. Probably the most important will be the decision as to what kind of man shall guide the technical college. In law, medical and theological schools, the lawyer, the doctor and the minister, respectively, hold first place and have much to say both in the actual training and in the management of the schools. Prominent members of the profession direct the destinies of the schools. To a much less extent do practising engineers influence the technical schools.

"The engineering college represents that form of scientific education most suitable to the exacting demands of advancing civilisation. The particular form of education which it gives through shop and laboratory practice, through practical tests, through acquaintance with the needs of industry, must not and will not be retarded by the classic heirlooms of the literary college. The engineering college must fill its own niche and work out its own salvation. Technical education is an educational and not an engineering problem.

"The technical college in which the future engineer is to be trained has several important characteristics to maintain. First, to educate scientifically and technically those who shall lead the march of the coming civilisation in industrial lines; second, to educate the public to a true sense of the value of applying scientific principles to industrial processes; third, as the university has for one of its functions the extension of human knowledge in any and all lines, so the technical colleges will recognise that the investigation of questions relating to applied science is within its own sphere of usefulness. Probably no investigation to-day would be more fruitful of good results to the engineering profession and to the public at large than the systematic study and thorough test of materials of construction. Such an investigation done on a large scale, on specimens of full building size, in a scientific manner, would save millions of dollars and put the science of construction on a scientific and economic basis. While the university asks no questions about the usefulness of the information gathered within its walls, the technical college must make its investigations in fields that are distinctly useful."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LORD AVEBURY referred to the neglect of scientific education in secondary schools, in an address delivered at Nottingham on Tuesday, before the Association of Chambers of Commerce of the United Kingdom. He pointed out that the public schools are legally bound, by the regulations made by Lord Salisbury's Royal Commission, to give in all examinations one-eighth of the marks for mathematics, one-eighth for modern languages, and one-eighth for science. How science fares may be judged by the fact that one public school with 900 boys has four science masters, and another with 500 boys only has three. In fact, the complaint made long ago by Ascham and Milton, and reiterated by Royal Commission after Royal Commission, still holds good to a great extent.

THE following list of successful candidates for Royal Exhibitions, National Scholarships, and Free Studentships (Science), 1901, has been issued by the Board of Education, South Kensington:—*Royal Exhibitions.*—Walter Smith, Henry F. C. Walsworth, Alec J. Simpson, James C. Smail, John Good, Sydney F. Paul, George E. Piper. *National Scholarships for Mechanics.*—George W. Phillips, Alfred W. Steed, David P. Grubb, Thomas G. John, Henry J. Jones. *Free Studentships for Mechanics.*—Herbert G. Tisdall, Thomas Chester. *National Scholarships for Physics.*—George W. Andrew, Leonard Southerns, John B. Homer, Sydney H. Higgins, Roger E. Grime. *Free Studentship for Physics.*—Otmar U. Seeman. *National Scholarships for Chemistry.*—Herbert B. P. Humphries, Alfred Shepherd, Alfred Berry, Donald Levy, Sydney H. Smith. *Free Studentships for Chemistry.*—Joseph A. Stokes, John F. Stansfield. *National Scholarships for Biology.*—Arthur R. Mynott, Alfred Eastwood, Richard C. Bristow, Malcolm Wilson. *Free Studentship for Biology.*—Florence E. Pratt. *National Scholarships for Geology.*—John E. Haworth, Claude G. Sara, Tobias Clegg.

THE candidates successful in the recent competition for the Whitworth Scholarships and Exhibitions are announced by the Board of Education, South Kensington, to be as follows:—Scholarships, 125*l.* a year each (tenable for three years)—Charles E. Handy, John E. Jagger, Albert Wilson, James C. Macfarlane. Exhibitions, 50*l.* (tenable for one year):—Thomas P. Shilston, Arthur Baker, George W. Phillips, George H. Andrews, John S. Nicholson, Henry F. C. Walsworth, Thomas G. John, Harry J. Wickham, John Good, James C. Smail, Gilmour E. Brown, George E. Piper, Alexander Gray, Arthur H. Sturdee, Harry Topham, Reginald Lavender, William H. Snow, Richard F. Barber, Harold Scragg, Harold E. Morrow, Thornton Knowles, John Ingham, Percy M. Bennett, Ernest G. Beck, Alfred G. Fox, Harold Fowler, Frank Lord, Thomas Chester, William E. Gardner, Roland W. Parry.

FROM particulars given in the thirteenth annual report just published by the National Association for the Promotion of Technical and Secondary Education, it appears that considerably over a quarter of a million of money (or 286,980*l.*) has become involved during the past year for the structural development of technical schools in England. If this sum be added to the trustworthy estimate of 2,643,172*l.* given in last year's report, it shows that the total amount incurred in England (excluding London) for 295 schools under municipal and public bodies is now at least 2,930,152*l.*; if all outlays upon other schools could be definitely assessed, this sum would doubtless reach more than 3,000,000*l.* (excluding London). The largest of the new building schemes is that of Bolton, the estimated capital outlay being 80,000*l.* The school will be established to a considerable degree upon Continental models, and will form one of the most important centres of technological training in the country. In Liverpool, 14,500*l.* is to be utilised for the equipment of a central technical school costing over 100,000*l.*; an important movement towards centralisation is consequently now taking place in that city.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 26.—M. Bouquet de la Grye in the chair.—Remarks by M. Janssen upon some observations of the Perseids from the Observatory at the summit of Mont Blanc.—On the application of the principle of energy to electrodynamic and electromagnetic phenomena, by M. E. Sarrau.—Critical remarks concerning the determination of sex in the Lepidoptera, by M. Alfred Giard. In discussing the results of the experiments of M. C. Flammarion upon the influence of colours in the production of the sexes in *Sericaria mori*, the author points out certain morphological data which modify the interpretation of the experiments considerably. In the opinion of the author, the great error of physiologists in studying questions of this order, as in many others, is in completely neglecting the morphological data, and in considering the animal or vegetable egg as a point of absolute departure, instead of a complex of energies accumulated by the varied conditions of existence or found in the ancestral organism.—On the mode of action of the brakes of automobiles, by M. A. Petot. From the formulæ usually employed to express the relation between the inertia and the co-efficient of adherence it can be deduced that it ought to be impossible to stop an electric tramway as rapidly as another vehicle, under similar conditions of speed and adherence. It is shown in the present note that this is an error, due to an inexact interpretation of the function of adherence during the application of the brake.—On the constitution of white light, by M. O. M. Corbino. According to M. Gouy, the different rays constituting the spectrum of white light are sinusoidal and perfectly regular components of one single complex vibration of any form whatever, and hence it follows that these components, their amplitude and phase remaining invariable, can interfere. According to M. Carvallo, the radiations separated by a grating are independent and consequently cannot interfere with each other. According to the author, the production of a system of mobile fringes in a channeled spectrum affords a crucial test of these two views. From these it is concluded that two radiations taken from different points of a continuous spectrum produced by white light are completely independent, and that in consequence it is impossible to consider them as two sinusoidal components of a single complex vibration.—The sexual elements and copulation in Stylorhynchus, by M. Louis Léger.—On a bacterial disease of the potato, by M. G. Delacroix. The disease in question, which is very prevalent in the centre and west of France, is due to a bacterium which appears to be identical with the *Bacillus Solanacearum* of E. F. Smith. It possesses the same characteristics on cultivation, and the symptoms of the disease observed in the United States on potatoes and tomatoes are similar to those observed in France. The only suggestion that can be put forward as a remedy is a triennial variation in the crops in order to clean the soil, which appears to be the vehicle of the disease, from the pathogenic organisms which it contains.—The invasion of streams of water in the department of Hérault by *Jussiaea grandiflora*, and on the growth of this species in France, by M. P. Carles. The growth of this plant in some districts is so great that it forms true aquatic prairies. It has been stated that this plant could not fructify in France, but this is now shown to be inaccurate, since in the month of September on the River Orb the fruit was formed in the shape of capsules about 29 mm. in length, each capsule having five divisions containing about fifteen seeds. It is by these seeds that it multiplies so abundantly.

CARNAC AND STONEHENGE.

(1) *The French Stonehenge: an Account of the Principal Megalithic Remains in the Morbihan Archipelago.* By T. Cato Worsfold, F.R.Hist.S., F.R.S.L. Pp. 44. (London: Bemrose and Sons, Ltd. No date.) Price 5*s*.

(2) *A Sentimental and Practical Guide to Amesbury and Stonehenge.* By Lady Antrobus. (Salisbury: Brown and Co., 1901.)

MR. WORSFOLD'S book, though the reason for its title, "Stonehenge," is not very apparent, gives a popular and interesting account of the wonderful megalithic works at Carnac, in Brittany. Those who desire to enter more deeply into the subject should consult "Les Alignments de Kermario," par James Miln Rennes (1881), a work which our author appears to have well studied, and "L'Astronomie Préhistorique," par F. Gaillard, dans la *Révue Mensuelle Internationale des Sciences Populaires* (15 Rue Lebrun, Paris).

Let us, however, accompany Mr. Worsfold in the slighter introduction which he gives. A lucid glance at the inhabitants of the district, which, with the peninsula of Quiberon, is part of the Department of Morbihan, is given in "Cæsar's Commentaries" (De Bello Gallico, iii. 3), describing his naval engagement with the Veneti, who seem to have been assisted by allies from Britain (Cæs., iv. 20). From this account it appears that the Veneti had evidently attained to no inconsiderable height of civilisation, as particularly shown in the construction and fittings of their ships. Our author adds the tradition that after their defeat the Veneti sailed away to the Mediterranean and founded the city of Venice. A description of Carnac follows.

The three great heads into which the megalithic remains may be divided are:—

(*a*) Menhirs, or single stones, in most cases upright, but occasionally overthrown. These, when they appear in circles, are called cromlechs.

(*b*) Dolmens, from Dol Men, a table stone consisting of a flat stone resting on two or more upright stones having subdivisions, "Dolmen a galérie" having an entrance way of sufficient height, and "Galgal," similar but smaller, "Dolmen à l'allée couverte" and "Kist-vaen," which should, indeed, be under another head, meaning stone coffins hewn out of one block.

(*c*) Alignments, which are lines of menhirs. These form the chief objects near Carnac. The finest dolmens are near Locmariaquer, a village about eight miles distant.

A large and lofty tumulus near Carnac, named Mont St. Michel, from a church so dedicated, which has been built upon it, has yielded on excavation many prehistoric relics; and near its base was found the remains of a Roman villa with Celtic or pre-Celtic relics arranged on shelves, showing that its Roman owner had been somewhat of an antiquarian. The name of the place is supposed to be derived from this tumulus or *cairn*. That this tumulus may have been connected originally with sun worship may be argued from the fact that the annual custom prevails of lighting a large bonfire on its summit at the time of the summer solstice, which is the signal for others to be kindled on similar prominent eminences for a distance of twenty or thirty miles round. These fires are called in the local patois "Tan Heol," and also by a later use, Tan St. Jean.

This practice prevailed also in Scotland under the name of Bel Tan, or Baal's Fire; the synonym for summer used by Sir Walter Scott in the "Lady of the Lake":—

> Ours is no sapling chance-sown by the fountain
> Blooming at Beltane in winter to fade.

The alignments of Carnac consist, firstly, of those known as "Le Menec," signifying *the place of stones*, or, by another interpretation, *the place of remembrance.* The next series are those of Kermario, or *the place of the dead.* The third series, Kerlescant, or *the place of burning.*

The alignments of Menec consist of eleven lines of menhirs, terminating towards the west in a cromlech, and notwithstanding that great numbers have been converted to other uses, still contain 1169 menhirs; some, however, do not exceed 18 inches in height, but others reach as much as 18 feet.

The alignments of Kermario in ten lines contain 989 menhirs. That of Kerlescant, which beginning with eleven rows is afterwards increased to thirteen, contains altogether 579 stones and thirty-nine in its cromlech, with some additional stones in a northerly direction. Each of these three alignments has its own orientation, and the large menhirs at the ends are supposed by some persons to mark the rising and setting of the sun, in some cases at the equinoxes and others at the solstices. In connection with this it is interesting to state that at Kerlescant the winter solstice is celebrated by a holiday, whilst Menec greets the summer solstice, and Kermario the equinoxes, with festivals. It appears that the adoration paid these stones remained strongly rooted for many centuries and yielded very slowly to Christianity. This is shown by the constant denunciations made against it in different countries. In the church history of Brittany in particular, the *Cultus Lapidum* was denounced in 658 A.D., and a decree was passed at Nantes that trees so worshipped should be torn up and burnt and stones cast down and hidden from those who sought to do them reverence. Indeed, the author quotes M. de Fréminville, who writes:—

> "On sait qu'au dix-septième siècle même l'idolâtrie était encore exercée dans l'isle d'Ouessant [*i.e.* Ushant] et dans plusieurs paroisses de l'évêché de Vannes." [Vannes is about twenty miles distant from Carnac.]

In connection with this it is stated that some years since a large number of these menhirs were lying prone on the ground exactly due north and south, and were subsequently restored to their original position by the French Government. These stones may have been overturned in compliance with the decree of 658 A.D. above referred to. Several of the loftier menhirs have been surmounted by crosses of stone or iron, so as to convert, at any rate, the appearance of veneration into an orthodox channel.

After a digression upon Stonehenge, presumably for the purpose of justifying the title of the book, but in which no very apparent analogy is pointed out, he cites Avebury, where it may be admitted that the character of the stones, but not the arrangement, is more suited for comparison. He returns to Morbihan and describes the monuments near Locmariaquer, and especially the "Dolmen des Marchands," about two miles from the village, where a granite block about 36 feet in length is poised in a horizontal position upon three others 16 feet high, the under surface being carved in a curious manner with undulating grooves and with hieroglyphics of axes interspersed. Then follows the account of a huge stone now lying on the ground which has been broken into five pieces, but presumably was once erect and stood 78 eet in height and 13 feet across at the base, weighing about 340 tons.[1]

Near Locmariaquer in the estuary named Riviere d'Auray, there is an island named Gavr' Inis, or Goat Island, which contains a good specimen of the kind of dolmen which has been named "Galgal."

"At the entrance our attention is at once arrested by the profusion of tracery which covers the walls. From the entrance to the wall facing us the distance is between 50 and 60 feet. The square chamber to which the gallery leads is composed of two huge slabs, the sides of the room and gallery being composed of upright stones, about a dozen on each side. The mystic lines and hieroglyphics similar to those above mentioned appear to have a decorative character."

An interesting feature of Gavr' Inis is its remarkable resemblance to the New Grange tumulus at Meath. In construction there is again a strong resemblance to Mæs-Howe, in the island of Orkney. There is also some resemblance in smaller details.

In excavations near Carnac and Locmariaquer, many curious prehistoric implements and ornaments have been discovered, which are preserved in the Miln museum at Carnac and in a museum at Vannes.

The main purpose of Lady Antrobus' sentimental and practical guide is to give a popular account of the interesting objects in the neighbourhood of Stonehenge, and especially of Stonehenge itself, and in this it succeeds admirably. The sentimental part is very well worth reading, but it is more in accordance with the intention of this article to proceed to the practical part, which is a very useful *résumé* of the chief authorities on the subject, and it is illustrated by some well-chosen photographs. The account begins with a translation from Diodorus Siculus, who lived about B.C. 8.

Hecatæus, the Milesian (who lived about 500 years B.C.), gives us the following story :—

"Over against Gaul, in the great ocean stream, is an island not less in extent than Sicily, stretching towards the North. The inhabitants are called Hyperboreans. It is said that the soil is very rich and fruitful, and the climate so favourable that there are two harvests in every year. There is in this island a magnificent temple to Apollo, circular in form, and adorned with many splendid offerings; and there is also a city sacred to Apollo, inhabited principally by harpers who in his temple sing sacred verses to the God. . . . Once in nineteen years (and this period is what we call the great year) they say that their God visits the island, and from the Vernal Equinox to the rising of the Pleiades (about May 1) all the night through expresses his satisfaction by dances and by playing on the harp."

The first author who is considered to make unmistakable mention of Stonehenge is Henry of Huntingdon (twelfth century). He speaks of it as the second wonder in England, and calls it Stanenges. Geoffry of Monmouth (A.D. 1138) wrote of it about the same time, as did his contemporary, Giraldus Cambrensis.

Langtoft, in his chronicle, tells a curious story :—

"A wonder wit of Wiltshire, rambling to Rome to gaze at antiquities, and there screwing himself into the company of antiquarians, they intreated him to illustrate to them that famous monument in his country called 'Stonage.' His answer was that he had never seen it, whereupon they kicked him out of doors and bade him go home and see Stonehenge."

Pepys says the stones are "as prodigious as any tales I have ever heard of them, and worth going this journey to see."

Mr. E. S. Maskelyne, in a lecture read 1897, called "The Age and Purpose of Stonehenge," fixes its date as 900 or 1000 B.C. (a date which seems sufficiently nearly confirmed by recent researches). Mr. Maskelyne proceeds :—

"I should like to add some reasons for my belief that Stonehenge was built by the Phœnicians. In the first place I cannot think of any other people that could either have designed or executed such a monument, which required both science for its conception and skill for its erection. The Phœnicians, with their familiarity with masts, cordage and pulleys could easily lift the imposts, and they must have known how the Egyptians raised masses of stone many times heavier.

"The trilithon standing clear seems to have had some fascination for the Phœnicians. They are found still standing in Tripoli in Libya, and specimens exist on the continent of Europe in Normandy and Brittany. One may be seen in the island of Ushant and another in St. Nazaire on the probable route they adopted for the carriage of tin. . . .

"About B.C. 400 the Greeks supplanted the Phœnicians in their trade with Britain. . . . Stonehenge must have been a noted temple, and I cannot doubt that Hecatæus did allude to it in the sixth century B.C. as the round temple of Apollo in the land of the Hyperboreans.

"As to the kinds of stone employed in the building, the whole of the outer circle and the four stones beyond that circle are undoubtedly 'Sarsen,' which are boulders left by the ice-sheet of the Glacial period on the Wiltshire Downs. In the inner circle are four stones of *whinstone*, an impure ironstone; the remainder are syenite, commonly called bluestones, and identical with those found on Dartmoor and many parts of Devon and Cornwall, the *altar-stone* being a kind of coarse blue marble, perhaps from Derbyshire."

Stonehenge stands about 440 feet above the sea-level. The outer circle measures 308 (330 externally). These stones formerly stood 14 feet above the surface of the ground. The uprights are unhewn, but have knobs or tenons on the top which fitted into mortise-holes on the underside of the horizontal stones, which were roughly squared.

Within this peristyle was the inner circle, composed mainly of unhewn syenite obeliscs, and then the great ellipse, formed of five (but some think seven) huge trilithons, which rose progressively in height from N.E. to S.W., the loftiest uprights being 25 feet above the ground. Of these remain two perfect trilithons and two of the upright stones, but of these one is much inclined from the vertical. The fall of one of the trilithons took place in A.D. 1620, owing to some injudicious excavations

[1] 240 in the text, but from other accounts this must be an error.

of the then Duke of Buckingham. Another fell in 1797, owing to the action of the weather upon its foundations.

The entrance to Stonehenge faced the N.E., and the road to it, or "Via Sacra," called the Avenue, can be traced by banks of earth which fall into those of the circumscribing circle of the earth bank which surrounds the whole structure, and which has a diameter of about 200 feet.

Prof. W. M. Flinders Petrie's account is cited as arriving at a date very much later than that given by Mr. Maskelyne, viz. as between 500 and 900 A.D.!

Lady Antrobus' book concludes with an account of the objects met with on the picturesque road which leads from Amesbury to Salisbury along the banks of the Avon.

OUR BOOK SHELF.

Polyphem ein Gorilla. By Dr. Th. Zell. Pp. 184. (Berlin: W. Junk, 1901.) Price Mk. 2.50.

A BOOK of nearly two hundred octavo pages of close print, discussing the subject above mentioned, may, without exaggeration, be termed exhaustive. It should be at once added, however, that in his preface the author refers expressly to those of the fifteen chapters (viz. Nos. xiii and xiv) which contain the essential arguments in support of his views. Otherwise the reader should be prepared to find himself involved in the consideration of the behaviour of animals in relation to changes in the weather, or engaged in the study of the relative keenness of the special senses of the walrus. The effects of meteorological changes on animals are discussed in reference to the story, not of Polyphemus, but of Proteus, in the course of a general disquisition on the interpretation of Homeric myths, while the subject of the special senses appears in subtle connection with important questions raised by the peculiar cyclopian eye of Polyphemus. The author's enthusiasm and his desire to examine all sides of the question have led him to burden his work with a large amount of detail, which could have been largely avoided, without diminishing the value of the book, by the substitution of reference for quotation *in extenso*.

The contributions to Homeric literature consist, firstly, in the exposition of the view expressed in the title of the book, viz., that the story of Polyphemus is not, as Grimm and others believe, a mystic account of the strife of the elements or a solar myth, but rather the reminiscence of an encounter of early civilised man with a pre-human ancestor. To this ancestor Dr. Zell prefers to refer as a "gorilla-mensch," reminding one of Winwood Reade's implied suggestion that Caliban was a gorilla.

In the second place, Dr. Zell suggests that the term cyclopian indicates that the person or animal so designated had simply eyes of rounded appearance and was not necessarily the possessor of a single median organ of sight.

While agreeing with Dr. Zell that the explanation of the story of Polyphemus is to be sought in the actual adventures of early voyagers, rather than in an appeal to the unaided inventive faculty of a poet, it is thought that the term "gorilla-mensch," as well as the title of the book, are distinctly unfortunate, as tending to revive the now discarded view that the particular ape in question should be regarded as figuring in the line of human ancestry. If the large gorilla mentioned on p. 112 is that which has been recently represented in certain publications in England and Germany, it is thought that Dr. Zell has been misled; for the attitude of the specimen referred to is not warranted by the structural anatomy of the gorilla.

With regard to the explanation of the term κύκλωψ, it must be admitted that this is a subject for inquiry on the part of philologists rather than students of natural science. Two remarks may be made here. The ordinarily accepted significance is one of very ancient standing. At the same time it is far more essential to Grimm's explanation than to that of Dr. Zell. W. L. H. D.

The Evolution of Consciousness. By Leonard Hall, M.A. Pp. 152. (London: Williams and Norgate, 1901.) Price 3s. net.

THIS is one of those well-meaning but futile books which it is almost impossible to criticise. To write a history of the evolution of consciousness an author should be thoroughly well informed of the latest results in both psychology and physiology. Mr. Hall seems to depend for his knowledge of the two sciences principally on the late J. S. Mill, with an infusion of Mr. Herbert Spencer. His account of psychological development is, no doubt unconsciously, entirely at variance with the results which have been won in recent years by careful experimentation, especially in the important domains of animal psychology, the analysis of spatial perception and the investigation of the processes by which meaning is acquired. The physiological explanations in which the writer indulges most frequently amount to nothing more than the reiteration of the blessed words "integration" and "differentiation." His grand thesis is that human consciousness is the property of a dominant cell or monad, but he seems not to be aware of the practical dethronement of the cell by the neuron as the unit of nervous action, nor does he offer any valid reason for his belief that the sub-cortical and medullary cells have a minor consciousness of their own. The actual "transference of consciousness" from one cell to another of which he talks freely is, of course, nonsense. Like most writers whose knowledge of psychology is of the same kind as his own, he is a very dogmatic and determined adherent of the merely mechanical theory of human action.

The Self-Educator in Chemistry. By James Knight, M.A., B.Sc., F.C.S., F.G.S., F.E.I.S. Edited by John Adams, M.A., B.Sc. Pp. xxiv + 162. (London: Hodder and Stoughton, 1901.) Price 2s. 6d.

THE intention and hope of the series to which this book belongs is that "the most isolated student will be able, without other aid, to ground himself in the various subjects dealt with." It is much to be doubted whether Mr. Knight's book will achieve any such purpose. Grounding in a subject is usually held to mean the laying down of substantial foundations, whereas this book is calculated rather to give superficial and miscellaneous information. It will give the reader no idea of the methods by which the principles of chemistry have been established, how chemical knowledge grows, or how chemists work and think. Within the first four pages the reader is introduced to atoms and molecules, graphic formulæ and the mysteries of the nascent state, whilst on the fifth he is told, "the statement that the atomic weight of oxygen is 16, means that a cubic inch, say, of oxygen is 16 times as heavy as a cubic inch of hydrogen. The atomic weight of substances like copper and carbon, which are not gases at all, are got in a more round-about fashion."

The most that can be said for the book is that it aims at showing chemistry in its relation to the things and phenomena of daily life. But it is neither thorough nor accurate, and doubts must arise as to the claims of a populariser who, besides propounding theory in the manner illustrated above, gets so far wrong in matters of fact as, for example, to state (p. 42) that hydrogen is liberated when steam is passed over red-hot copper, and that water gas and producer gas have the same composition. A. S.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Density and Figure of Close Binary Stars.

WHEN one star revolves round another in an orbit of which the plane is coincident, or nearly so, with the line of sight, an eclipse of one star by the other will take place every revolution. We have, in such circumstances, the well-known phenomenon of Algol variation.

It is evident that the duration, extent, and nature of the eclipse will depend upon the size and brightness of the component stars, and on the magnitude, inclination, and eccentricity of the orbit in which they move.

In practice, of course, the problem is the indirect one of determining the elements of orbital movement of the system from the observed variation in the star's brightness. That is to say, having ascertained, either photometrically or photographically, the manner in which the light of the star varies, we determine the physical conditions which have produced this variation.

There is no field of astronomical research in the present day so interesting, or so rich in future possibilities, as that which deals with close binary stars. We have only to instance the recent discovery, by Prof. W. W. Campbell, of the Lick Observatory, that at least one star in every five or six is a spectroscopic binary (*Astrophysical Journal*, vol. xiii. p. 89), as an indication of the vastness of the field.

If Prof. Campbell's estimate of the number of binary systems be correct, then there ought, on the consideration that such systems may revolve in any plane, to be at least 800 Algol variables brighter than the ninth magnitude. At present only twenty-two such systems are known to astronomers.

Then, again, the certainty that in variable stars of the Algol type—that is, binary stars revolving round one another almost or *actually in* contact—we have the first stage in the evolution of a stellar system, gives a unique interest to any investigation, whether spectroscopic or photometric, which has as its purpose the delineation of the conditions of magnitude and movement of such systems.

Of the many problems intimately related to a determination of the elements of orbital movement of any close binary system, two are, I think, of peculiar interest, as bearing directly on the evolution of such systems.

(1) When we have ascertained the size and brightness of the component stars of any system, and also the form, position, and magnitude of the orbit in which they revolve, we can directly deduce the mean density of the system. A full investigation of this and allied problems is given by Mérian in *Comptes rendus* (122, 1254).

A nomenclature adopted by the present writer, in the *Astrophysical Journal* (vol. x. p. 308), meets, I think, more directly the simpler conditions of the problem of the density of a close binary star.

Putting t = time, in days, of revolution;
r = semi-axis major of the orbit of the system;
p = ratio of the radius of companion (1) to semi-axis major;
q = ratio of the radius of companion (2);
m_1 = mass of companion (1);
m_2 = mass of companion (2);
Δ_1 = density of companion (1);
Δ_2 = density of companion (2);

(the sun's radius, mass and density are taken as unity) then the simple relation

$$\Delta_1 = \frac{0\cdot0135}{p^3t^2} \cdot \frac{m_1}{m_1 + m_2}, \quad . \quad . \quad . \quad . \quad (1)$$

$$\Delta_2 = \frac{0\cdot0135}{q^3t^2} \cdot \frac{m_2}{m_1 + m_2}, \quad . \quad . \quad . \quad . \quad (2)$$

will determine the values of Δ_1 and Δ_2 when the relative masses of the two component stars are known.

If $$p = q,$$

then $$\Delta_1 + \Delta_2 = \frac{0\cdot0135}{p^3t^2}. \quad . \quad . \quad . \quad . \quad . \quad (3)$$

It will be at once evident that, since

$$\frac{m_1}{m_1 + m_2} \text{ and } \frac{m_2}{m_1 + m_2}$$

must always be less than unity,

$$\Delta_1 < \frac{0\cdot0135}{p^3t^2};$$

$$\Delta_2 < \frac{0\cdot0135}{q^3t^2}.$$

These two relations express the limit in one direction of the density of any binary system when the size of the component stars, and the period of variation, has been ascertained from an examination of the light-curve of the variable. In the *Astrophysical Journal* (vol. x. p. 315), Prof. H. N. Russell, of the Princeton University, from considerations similar to the foregoing, deals with the light-variation of seventeen out of the twenty-two Algol variables, deducing from their variation their densities.

He finds the mean density of the seventeen stars considered to be

0·19,

the density o. water being unity.

In the same *Journal* (vol. x. p. 314), the writer discussed the light-changes of four southern Algol variables which had been under observation for some years at Lovedale, South Africa.

The mean density of these four stars was found to be 0·13 that of the sun. If the sun's density be taken as 1·44 times the density of water, then this result would yield as the mean density of the stars considered,

0·187.

Since this article was written, two new southern Algol variables have been discovered—one at the Cape Royal Observatory and the other at Lovedale. Further, a new photometric equatorial, specially constructed by Messrs. Cooke for variable star work, has made it possible to secure observations, at Lovedale, of all the eight southern Algol variables of considerable accuracy.

A reduction of these observations has just been completed, and an examination of the results gives, as the mean density of all the southern Algol variables at present known, viz. eight, the value

0·176.

Of the three investigations just given in brief, the first two were independently conceived, carried out, and completed. Yet the results are practically accordant.

There is just the barest possibility that this agreement may be fortuitous; such a remote possibility exists in all investigations.

It is much more probable, however, that the agreement between the results indicates the truth of the conclusion. And this conclusion is that the average density of close binary stars—that is, of bodies just forming, by the compulsion of their inherent forces, into a dual existence—is one-sixth that of water or one-eighth that of the sun.

It is not the purport of the present paper to follow the investigation to its legitimate termination—that is, to discover in what agreement is the result just obtained with the theoretical conditions of density consonant with a rotating ellipsoid on the limit of bipartition. A broad general agreement, however, is evident even on an elementary judgment, for if the result had been that the average density of close binary systems, or of the actual density of any one system, was, say, much greater than that of the earth, then it would be difficult to understand how separation could take place under these conditions. On the other hand, no violence is done to our appreciation of what is reasonable when we find that *all* close binary systems have a density much less than water; in some single cases, indeed, we meet with densities approaching that of a gaseous nebula. Such a condition of tenuity is evidently favourable to disruption.

Any investigation of the light-changes of an Algol variable, having extreme accuracy in view, must of necessity consider the form of the stars alternately eclipsing one another.

It is evident that the rate of decrease or increase of eclipse will be more rapid the more ellipsoidal in figure the component stars are.

In the case of two spheres eclipsing one another, the amount of obscuration, or the total amount of light emitted by the system, at any period of the eclipse, can be ascertained from the simplest geometrical considerations. In the case of two spheroids, the computation is not so simple.

Still a relation does exist between the amount of distortion due to the mutual attractions of two adjacent bodies, and the rate of obscuration in any eclipse, and this relation is capable of discernment and computation. The difficulty, however, does not lie in the computation: it lies in our inability to determine observations refined enough to respond to a demand so exacting as that which necessitates observations correct to within two-hundredths of a magnitude.

That this degree of accuracy in photometric measurement has been attained to by more than one observer brings the problem of the determination of the figure of a rotating binary system within a reasonable expectation of solution.

Of the twenty-two Algol variables at present known, five are binary systems the component stars of which revolve in contact. It is, therefore, evident that any investigation having as its purpose the figure of the component members of a close binary system should deal first with these five stars.

Particulars of these stars are as follows:—

Chandler No.	Designation.	R.A. 1900.	Decl. 1900.	Period.	Max.	Min.
		h. m. s.	° ′	d. h. m. s.	m.	m. m.
2852	V Puppis	7 55 22	−48 58·4	1 10 54 27	4·1	4·7—4·9
3055	X Carinae	8 29 7	−58 53·2	1 1 59 0	7·9	8·6—8·7
5099	RR Centauri.	14 9 55	−57 23·3	0 14 32 7	7·4	7·8—7·85
6758	β Lyræ	18 46 23	+33 14·8	12 21 46 58	3·4	3·9—4·5
8598	U Pegasi	23 52 53	+15 23·9	0 8 59 41	9·3	9·8—9·9

It may be objected that all along it has been assumed that Algol variables are binary systems. What evidence is there that this is so?

In the only cases where independent confirmation is possible—that is, in cases where the stars are bright enough to be dealt with spectroscopically—this confirmation is forthcoming.

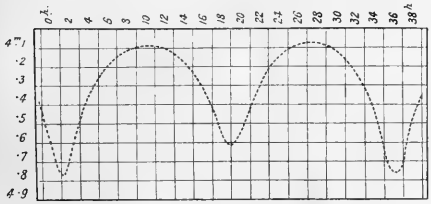

FIG. 1.—Light-curve of V Puppis, from observations made at Lovedale South Africa.

With regard to the foregoing five stars, the spectroscope reveals V Puppis and β Lyræ to be binary systems. The other stars are beyond the reach of spectroscopic examination, at least with its present limitations.

Apart from this, however, revolution and consequent eclipse is the only complete explanation of Algol variation.

In Fig. 1 is given the light-curve of V Puppis, the first star in the list, and this light-curve may be taken as typical of those of the other four stars. Indeed, the light-curve of U Pegasi (*Harvard Circular*, No. 23) is practically identical with that of V Puppis.

The figure of the β Lyræ system has been considered most fully and conclusively by Mr. Myers in the *Astrophysical Journal* (vol. vii. p. 1); one of his definite results being that each star forming the system is not a sphere but an ellipsoid of revolution. The amount of flattening is found to be 0·2 in both stars.

Mr. Myers also deals with the variation of U Pegasi in the same manner (*Astrophysical Journal*, vol. viii. p. 163), and finds that there is distinct evidence, in the form of the light-curve of this star, of an ellipsoidal figure in both components.

In the *Astrophysical Journal* (vol. xiii. p. 177), the writer considered the variation of V Puppis, the first of the five stars. Again it was found that while, to no insufficient extent, the view that the light-changes were produced by the eclipse of two spheres would meet the facts of variation, an assumption that both components were ellipsoidal in figure would satisfy the observations more fully.

Since the foregoing article was published, an examination of all the observations of X Carinæ and RR Centauri made at Lovedale has been completed. It is found that the twin stars of X Carinæ have parted company. They are no longer in actual contact, although a distance of only one-tenth of their diameters separates them. The observations of this star also do not indicate an unmistakable distortion of either component.

In the case of RR Centauri we have a twin system similar to that of V Puppis, with this difference, that the form of the light-curve indicates beyond doubt a considerable ellipsoidal form of both stars. Indeed, a dumb-bell figure of equilibrium similar to that indicated in Prof. Darwin's treatise on "Figures of Equilibrium of Rotating Masses of Fluid" (p. 429) would produce variation of the same character as that of RR Centauri.

Of the interest which attaches to all investigations, whether by telescope or spectroscope, concerning these remarkable binary systems, there can be no manner of doubt. For we are dealing with the origin of stellar systems.

Hitherto, in theory only have we had cognisance of some great gaseous orb aggregating itself into two elongated spheroids, dividing after the lapse of long ages into two separate and distinct bodies.

By the action and interaction of their tidal forces, the gap between the component stars grows wider and wider: the system ceases to be a close binary star fulfilling its period in days; it takes months to complete its circuit.

And still the apocentric revolution goes on, until, at last, the star becomes a visual binary, one component separated from its fellow by the width of the whole solar system.

From V Puppis, on the one hand, a dumb-bell system speeding round in thirty-five hours, to the twin stars of Castor, completing their great round in one thousand years, we have a regular chain of sequences in distance.

The links of this chain are made evident by observation as well as by theory. It is not unreasonable, therefore, that the present trend of astrophysical research should be in the direction of discovering more fully and certainly the different stages of evolution and development in the architecture of the heavens.

ALEX. W. ROBERTS.

Lovedale, South Africa, August 9.

A Plea for a Prehistoric Survey of Southern India.

ACCORDING to Mr. R. Bruce Foote, and no one is more competent to speak than he, the urgency for the establishment of a genuine prehistoric survey in Southern India is very great, if the study of this most fascinating branch of archæology is to be encouraged and the wanton destruction of prehistoric monuments checked. Such survey, if honestly carried out, would go far to procure much larger data than yet exist as to the distribution over the southernmost districts of the peninsula of the Palæolithic people whose remains in the shape of chipped stone implements have been found in so many localities in the Carnatic and Deccan plateau, embedded in Pleistocene deposits. Such data might help materially also to bridge over the great hiatus in time which now appears to exist between the era of those very rude people and that of the Neolithic tribes which followed them in the same country.

Further research in the southern districts especially might result in the finding of evidence as to the quarter from which the Dravidian tribes entered the Peninsula—a question of very high ethnological interest.

Another very important ethnological question might possibly be also answered by such investigations, namely, were the first Dravidian immigrants that settled in Southern India in a Neolithic stage of culture, or must the polished-stone people be considered as pre-Dravidian? If the question be answered in the latter way, a fresh immigration must be postulated, by which the true Dravidians reached their present country. If the answer affirms the former proposition, the idea of a further immigration may be dispensed with, for the early iron people appear to be the direct descendants of the Neolithic tribes and the ancestors of the present inhabitants.

Every year numbers of prehistoric burial places are destroyed by the rapacity of the "Waddars," the wandering tribe of tank diggers, who are allowed to annex the fine slabs composing the *kistvaens*, while independent archæologists are, by Government order, forbidden to open any old graves unless they are willing to make over to the Museum all their finds and bear their own expenses. The lapse of time and effects of weather greatly tend to diminish the remains of the old people in the sites they occupied. The action of the plough in many cases, and the trampling of herds of cattle in others, are active elements of destruction of pottery buried near the surface, and even of stone implements. These remarks apply with equal force to the old sites of the early iron age folk, both residential and sepulchral.

Mr. Foote further states in his "Catalogue of the Prehistoric Antiquities" in the Government Museum at Madras, that a full and exhaustive prehistoric survey of the country should be made by a really competent specialist, who shall be a geologist and an osteologist as well as a trained archæologist, and not a mere architectural surveyor. A knowledge of Sanskrit will be of no use in deciding as to the sources whence were derived the many foreign rocks and minerals found in the many old residential sites, which, up to date, have had only their surfaces examined, but which, doubtless, in many cases will yield rich finds to the careful excavator, who must be a man having the power to devote time to his work. A. C. HADDON.

Cambridge, September 3.

THE BRITISH ASSOCIATION AT GLASGOW.

IN the previous articles, which appeared in NATURE, May 23, July 18, and August 22, particulars were given as to the local arrangements for the meeting in Glasgow, and a forecast of the papers to be read at the sectional meetings was published. The president, Principal A. W. Rücker, delivered his presidential address, which we print in this issue, as we went to press yesterday, and the business of the sections commenced this morning. A large number of British leading men of science are present at the meeting, and many well-known men of science are also present from abroad. Among others, the following are attending the meeting:—Prof. L. Kny, Berlin; Prof. George Quincke, Heidelberg; Prof. G. Mittag-Leffler, Stockholm; Dr. Gustav Cassil, Copenhagen; Prof. A. F. Renard, Ghent; Prof. Gustave Gilson, Louvain; Mr. A. Laurence Rotch, Readville, Mass., U.S.A.; Prof. R. H. Thurston, Cornell University; Dr. T. P. Lotsy, Arnheim, Holland; Dr. Theodor Beer, Vienna; Prof. J. J. Mackenzie, Toronto; Prof. E. W. Morley, Cleveland, Ohio; Prof. Joji Sakurai, Tokyo; His Excellency Don Arturo de Marcoartu, Bilbao; Prof. J. P. McMurrick, Michigan; Dr. V. Crémieu, Paris; Prof. Dr. W. Marikwald, Berlin; Prof. Paul Walden, Riga; Prof. Goebel, Munich; Dr. C. E. Guillaume, Sevres; Dr. Conventz, Danzig; Baron Varilla, Paris; Mr. Edward Atkinson, Brooklyn; Prof. Anitchkoff, Russia.

The meeting promises to be a successful one, both from the point of view of numbers and that of scientific interest.

INAUGURAL ADDRESS BY PROF. ARTHUR W. RÜCKER, M.A., LL.D., D.SC., SEC.R.S., PRESIDENT OF THE ASSOCIATION.

THE first thought in the minds of all of us to-night is that since we met last year the great Queen, in whose reign nearly all the meetings of the British Association have been held, has passed to her rest.

To Sovereigns most honours and dignities come as of right; but for some of them is reserved the supreme honour of an old age softened by the love and benedictions of millions; of a path to the grave, not only magnificent, but watered by the tears both of their nearest and dearest, and of those who, at the most, have only seen them from afar.

This honour Queen Victoria won. All the world knows by what great abilities, by what patient labour, by what infinite tact and kindliness, the late Queen gained both the respect of the rulers of nations and the affection of her own subjects.

Her reign, glorious in many respects, was remarkable, outside these islands, for the growth of the Empire; within and without them, for the drawing nearer of the Crown and the people in mutual trust; while, during her lifetime, the developments of science and of scientific industry have altered the habits and the thoughts of the whole civilised world.

The representatives of science have already expressed in more formal ways their sorrow at the death of Queen Victoria, and the loyalty and confident hope for the future with which they welcome the accession of King Edward. But none the less, I feel sure that at this, the first meeting of the British Association held in his reign, I am only expressing the universal opinion of all our members when I say that no group of the King's subjects trusts more implicitly than we do in the ability, skill, and judgment which His Majesty has already shown in the exercise of the powers and duties of his august office; that none sympathise more deeply with the sorrows which two great nations have shared with their Sovereigns; and that none cry with more fervour, "Long live the King!"

But this meeting of the British Association is not only remarkable as being the first in a new reign. It is also the first in a new century. It is held in Glasgow at a time when your International Exhibition has in a special sense attracted the attention of the world to your city, and when the recent celebration of the ninth jubilee of your University has shown how deeply the prosperity of the present is rooted in the past. What wonder, then, if I take the Chair to which you have called me with some misgivings? Born and bred in the South, I am to preside over a meeting held in the largest city of Scotland. As your chosen mouthpiece I am to speak to you of science when we stand at the parting of the centuries, and when the achievements of the past and present, and the promise of the future, demand an interpreter with gifts of knowledge and divination to which I cannot pretend. Lastly, I am President of the British Association as a disciple in the home of the master, as a physicist in a city which a physicist has made for ever famous. Whatever the future may have in store for Glasgow, whether your enterprise is still to add wharf to wharf, factory to factory, and street to street, or whether some unforeseen "tide in the affairs of men" is to sweep energy and success elsewhere, fifty-three years in the history of your city will never be forgotten while civilisation lasts.

More than half a century ago, a mere lad was the first to compel the British Association to listen to the teaching of Joule, and to accept the law of the conservation of energy. Now, alike in the most difficult mathematics and in the conception of the most ingenious apparatus, in the daring of his speculations and in the soundness of his engineering, William Thomson, Lord Kelvin, is regarded as a leader by the science and industry of the whole world.

It is the less necessary to dwell at length upon all that he has done, for Lord Kelvin has not been without honour in his own country. Many of us, who meet here to-night, met last in Glasgow when the University and City had invited representatives of all nations to celebrate the Jubilee of his professorship. For those two or three days learning was surrounded with a pomp seldom to be seen outside a palace. The strange middle-age costumes of all the chief Universities of the world were jostling here, the outward signs that those who were themselves distinguished in the study of Nature had gathered to do honour to one of the most distinguished of them all.

Lord Kelvin's achievements were then described in addresses in every tongue, and therefore I will only remind you that we, assembled here to-night, owe him a heavy debt of gratitude; for the fact that the British Association enters on the twentieth century conscious of a work to do and of the vigour to do it is largely due to his constant presence at its meetings and to the support he has so ungrudgingly given. We have learned to know, not only the work of our great leader, but the man himself; and I count myself happy because in his life-long home, under the walls of the University he served so well, and at a meeting of the Association which his genius has so often illuminated, I am allowed, as your President, to assure him in your name of the admiration, respect, nay, of the affection, in which we all hold him.

I have already mentioned a number of circumstances which make our meeting this year noteworthy; to these I must add that for the first time we have a Section for Education, and the importance of this new departure, due largely to the energy of Prof. Armstrong, is emphasised by the fact that the Chair of that Section will be occupied by the Vice-President of the Committee of Council on Education—Sir John Gorst. I will not attempt to forecast the proceedings of the new Section. Education is passing through a transitional stage. The recent debates in Parliament; the great gifts of Mr. Carnegie; the discussion as to University organisation in the North of England; the reconstitution of the University of London; the increasing importance attached to the application of knowledge both to the investigation of Nature and to the purposes of industry, are all evidence of the growing conviction that without advance in education we cannot retain our position among the nations of the world. If the British Association can provide a platform on which these matters may be discussed in a scientific but practical spirit, free from the misrepresentations of the hustings and the exaggerations of the partisan, it will contribute in no slight measure to the national welfare.

But amid the old and new activities of our meeting the undertone of sadness, which is never absent from such gatherings, will be painfully apparent to many of us at Glasgow. The life-work of Prof. Tait has ended amid the gloom of the war-cloud. A bullet, fired thousands of miles away, struck him to the heart, so that in their deaths the father and the brave son, whom he loved so well, were not long divided. Within the last year, too, America has lost Rowland; Viriamu Jones, who did yeoman's service for education and for science, has succumbed to a long and painful illness; and one who last year at Bradford seconded the proposal that I should be your President at Glasgow, and who would unquestionably have occupied this Chair before long had he been spared to do so, has unexpectedly been called away. A few months ago we had no reason to doubt that George Francis FitzGerald had many years of health and work before him. He had gained in a remarkable way not only the admiration of the scientific world, but the affection of his friends, and we shall miss sadly one whom we all cared for, and who, we hoped, might yet add largely to the achievements which had made him famous.

The Science of the Nineteenth Century.

Turning from these sad thoughts to the retrospect of the century which has so lately ended, I have found it to be impossible to free myself from the influence of the moment and to avoid, even if it were desirable to avoid, the inclination to look backward from the standpoint of to-day.

Two years ago Sir Michael Foster dealt with the work of the century as a whole. Last year Sir William Turner discussed in greater detail the growth of a single branch of science. A third and humbler task remains, viz., to fix our attention on some of the hypotheses and assumptions on which the fabric of modern theoretical science has been built, and to inquire whether the foundations have been so "well and truly" laid that they may be trusted to sustain the mighty superstructure which is being raised upon them.

The moment is opportune. The three chief conceptions which for many years have dominated physical as distinct from biological science have been the theories of the existence of atoms, of the mechanical nature of heat, and of the existence of the ether.

Dalton's atomic theory was first given to the world by a Glasgow professor—Thomas Thomson—in the year 1807, Dalton having communicated it to him in 1804. Rumford's and Davy's experiments on the nature of heat were published in 1798 and 1799 respectively; and the celebrated Bakerian Lecture, in which Thomas Young established the undulatory theory by explaining the interference of light, appeared in the *Philosophical Transactions* in 1801. The keynotes of the physical science of the nineteenth century were thus struck, as the century began, by four of our fellow-countrymen, one of whom—Sir Benjamin Thompson, Count Rumford—preferred exile from the land of his birth to the loss of his birthright as a British citizen.

Doubts as to Scientific Theories.

It is well known that of late doubts have arisen as to whether the atomic theory, with which the mechanical theory of heat is closely bound up, and the theory of the existence of an ether have not served their purpose, and whether the time has not come to reconsider them.

The facts that Prof. Poincaré, addressing a congress of physicists in Paris, and Prof. Poynting, addressing the Physical Section of the Association, have recently discussed the true meaning of our scientific methods of interpretation; that Dr. James Ward has lately delivered an attack of great power on many positions which eminent scientific men have occupied; and that the approaching end of the nineteenth century led Prof. Haeckel to define in a more popular manner his own very definite views as to the solution of the "Riddle of the Universe," are perhaps a sufficient justification of an attempt to lay before you the difficulties which surround some of these questions.

To keep the discussion within reasonable limits, I shall illustrate the principles under review by means of the atomic theory, with comparatively little reference to the ether, and we may also at first confine our attention to inanimate objects.

The Construction of a Model of Nature.

A natural philosopher, to use the old phrase, even if only possessed of the most superficial knowledge, would attempt to bring some order into the results of his observation of Nature by grouping together statements with regard to phenomena which are obviously related. The aim of modern science goes far beyond this. It not only shows that many phenomena are related which at first sight have little or nothing in common, but, in so doing, also attempts to explain the relationship.

Without spending time on a discussion of the meaning of the word "explanation," it is sufficient to say that our efforts to establish relationships between phenomena often take the form of attempting to prove that, if a limited number of assumptions are granted as to the constitution of matter, or as to the existence of quasi-material entities, such as caloric, electricity, and the ether, a wide range of observed facts falls into order as a necessary consequence of the assumptions. The question at issue is whether the hypotheses which are at the base of the scientific theories now most generally accepted are to be regarded as accurate descriptions of the constitution of the universe around us, or merely as convenient fictions.

Convenient fictions be it observed, for even if they are fictions they are not useless. From the practical point of view it is a matter of secondary importance whether our theories and assumptions are correct, if only they guide us to results which are in accord with facts. The whole fabric of scientific theory may be regarded merely as a gigantic "aid to memory"; as a means for producing apparent order out of disorder by codifying the observed facts and laws in accordance with an artificial system, and thus arranging our knowledge under a comparatively small number of heads. The simplification introduced by a scheme which, however imperfect it may be, enables us to argue from a few first principles, makes theories of practical use. By means of them we can foresee the results of combinations of causes which would otherwise elude us. We can predict future events, and can even attempt to argue back from the present to the unknown past.

But it is possible that these advantages might be attained by means of axioms, assumptions, and theories based on very false ideas. A person who thought that a river was really a streak of blue paint might learn as much about its direction from a map as one who knew it as it is. It is thus conceivable that we might be able, not indeed to construct, but to imagine, something more than a mere map or diagram, something which might even be called a working model of inanimate objects, which was nevertheless very unlike the realities of Nature. Of course, the agreement between the action of the model and the behaviour of the things it was designed to represent would probably be imperfect, unless the one were a facsimile of the other; but it is conceivable that the correlation of natural phenomena could be imitated, with a large measure of success, by means of an imaginary machine, which shared with a map or diagram the characteristic that it was in many ways unlike the things it represented, but might be compared to a model in that the behaviour of the things represented could be predicted from that of the corresponding parts of the machine.

We might even go a step further. If the laws of the working of the model could be expressed by abstractions, as, for example, by mathematical formulæ, then, when the formulæ were obtained, the model might be discarded, as probably unlike that which it was made to imitate, as a mere aid in the construction of equations, to be thrown aside when the perfect structure of mathematical symbols was erected.

If this course were adopted, we should have given up the attempt to know more of the nature of the objects which surround us than can be gained by direct observation, but might nevertheless have learned how these objects would behave under given circumstances.

We should have abandoned the hope of a physical explanation of the properties of inanimate Nature, but should have secured a mathematical description of her operations.

There is no doubt that this is the easiest path to follow. Criticism is avoided if we admit from the first that we cannot go below the surface; cannot know anything about the constitution of material bodies; but must be content with formulating a description of their behaviour by means of laws of Nature expressed by equations.

But if this is to be the end of the study of Nature, it is evident that the construction of the model is not an essential part of the process. The model is used merely as an aid to thinking; and if the relations of phenomena can be investigated without it, so much the better. The highest form of theory—it may be said—the widest kind of generalisation, is that which has given up the attempt to form clear mental pictures of the constitution of matter, which expresses the facts and the laws by language and symbols which lead to results that are true, whatever be our view as to the real nature of the objects with which we deal. From this point of view the atomic theory becomes not so much false as unnecessary; it may be regarded as an attempt to give an unnatural precision to ideas which are and must be vague.

Thus, when Rumford found that the mere friction of metals produced heat in unlimited quantity, and argued that heat was therefore a mode of motion, he formed a clear mental picture of what he believed to be occurring. But his experiments may be quoted as proving only that energy can be supplied to a body in indefinite quantity, and when supplied by doing work against friction it appears in the form of heat.

By using this phraseology we exchange a vivid conception of moving atoms for a colourless statement as to heat energy, the real nature of which we do not attempt to define; and methods which thus evade the problem of the nature of the things which the symbols in our equations represent have been prosecuted with striking success, at all events within the range of a limited class of phenomena. A great school of chemists, building upon the thermodynamics of Willard Gibbs and the intuition of Van t' Hoff, have shown with wonderful skill that, if a sufficient number of the data of experiment are assumed, it is possible, by the aid of thermodynamics, to trace the form of the relations between many physical and chemical phenomena without the help of the atomic theory.

But this method deals only with matter as our coarse senses know it; it does not pretend to penetrate beneath the surface.

It is therefore with the greatest respect for its authors, and with a full recognition of the enormous power of the weapons employed, that I venture to assert that the exposition of such a system of tactics cannot be regarded as the last word of science in the struggle for the truth.

Whether we grapple with them, or whether we shirk them; however much or however little we can accomplish without answering them, the questions still force themselves upon us: Is matter what it seems to be? Is interplanetary space full or empty? Can we argue back from the direct impressions of our senses to things which we cannot directly perceive; from the phenomena displayed by matter to the constitution of matter itself?

It is these questions which we are discussing to-night, and we may therefore, as far as the present address is concerned, put aside, once for all, methods of scientific exposition in which an attempt to form a mental picture of the constitution of matter is practically abandoned, and devote ourselves to the inquiries whether the effort to form such a picture is legitimate, and whether we have any reason to believe that the sketch which science has already drawn is to some extent a copy, and not a mere diagram, of the truth.

Successive Steps in the Analysis of Matter.

In dealing, then, with the question of the constitution of matter and the possibility of representing it accurately, we may grant at once that the ultimate nature of things is, and must remain, unknown; but it does not follow that immediately below the complexities of the superficial phenomena which affect our senses there may not be a simpler machinery of the existence of which we can obtain evidence, indirect indeed, but conclusive.

The fact that the apparent unity which we call the atmosphere can be resolved into a number of different gases is admitted; though the ultimate nature of oxygen, nitrogen, argon, carbonic acid, and water vapour is as unintelligible as that of air as a whole, so that the analysis of air may be said to have substituted many incomprehensibles for one.

Nobody, however, looks at the question from this point of view. It is recognised that an investigation into the proximate constitution of things may be useful and successful, even if their ultimate nature is beyond our ken.

Nor need the analysis stop at the first step. Water vapour and carbonic acid, themselves constituents of the atmosphere, are in turn resolved into their elements, hydrogen, oxygen, and carbon, which, without a formal discussion of the criteria of reality, we may safely say are as real as air itself.

Now, at what point must this analysis stop if we are to avoid crossing the boundary between fact and fiction? Is there any fundamental difference between resolving air into a mixture of gases and resolving an elementary gas into a mixture of atoms and ether?

There are those who cry halt! at the point at which we divide a gas into molecules, and their first objection seems to be that molecules and atoms cannot be directly perceived, cannot be seen or handled, and are mere conceptions, which have their uses, but cannot be regarded as realities.

It is easiest to reply to this objection by an illustration.

The rings of Saturn appear to be continuous masses separated by circular rifts. This is the phenomenon which is observed through a telescope. By no known means can we ever approach or handle the rings; yet everybody who understands the evidence now believes that they are not what they appear to be, but consist of minute moonlets, closely packed indeed, but separate the one from the other.

In the first place, Maxwell proved mathematically that if a Saturnian ring were a continuous solid or fluid mass it would be unstable and would necessarily break into fragments. In the next place, if it were possible for the ring to revolve like a solid body, the inmost parts would move slowest, while a satellite moves faster the nearer it is to a planet. Now, spectroscopic observation, based on the beautiful method of Sir W. Huggins, shows not only that the inner portions of the ring move the more rapidly, but that the actual velocities of the outer and inner edges are in close accord with the theoretical velocities of satellites at like distances from the planet.

This and a hundred similar cases prove that it is possible to obtain convincing evidence of the constitution of bodies between whose separate parts we cannot directly distinguish, and I take it that a physicist who believes in the reality of atoms thinks that he has as good reason for dividing an apparently continuous gas into molecules as he has for dividing the apparently continuous Saturnian rings into satellites. If he is wrong, it is not the fact that molecules and satellites alike cannot be handled and cannot be seen as individuals, that constitutes the difference between the two cases.

It may, however, be urged that atoms and the ether are alleged to have properties different from those of matter in bulk, of which alone our senses take direct cognisance, and that therefore it is impossible to prove their existence by evidence of the same cogency as that which may prove the existence of a newly discovered variety of matter or of a portion of matter too small or too distant to be seen.

This point is so important that it requires full discussion, but in dealing with it, it is necessary to distinguish carefully between the validity of the arguments which support the earlier and more fundamental propositions of the theory; and the evidence brought forward to justify mere speculative applications of its doctrines which might be abandoned without discarding the theory itself. The proof of the theory must be carried out step by step.

The first step is concerned wholly with some of the most general properties of matter, and consists in the proof that those properties are either absolutely unintelligible, or that, in the case of matter of all kinds, we are subject to an illusion similar to that the results of which we admit in the case of Saturn's rings, clouds, smoke, and a number of similar instances. The believer in the atomic theory asserts that matter exists in a particular state; that it consists of parts which are separate and distinct the one from the other, and as such are capable of independent movements.

Up to this point no question arises as to whether the separate parts are, like grains of sand, mere fragments of matter; or whether, though they are the bricks of which matter is built, they have, as individuals, properties different from those of masses of matter large enough to be directly perceived. If they are mere fragments of ordinary matter, they cannot be used as aids in explaining those qualities of matter which they themselves share.

We cannot explain things by the things themselves. If it be true that the properties of matter are the product of an underlying machinery, that machinery cannot itself have the properties which it produces, and must, to that extent at all events, differ from matter in bulk as it is directly presented to the senses.

If, however, we can succeed in showing that if the separate parts have a limited number of properties (different, it may be, from those of matter in bulk), the many and complicated properties of matter can, to a considerable extent, be explained as consequences of the constitution of these separate parts; we shall have succeeded in establishing, with regard to quantitative properties, a simplification similar to that which the chemist has established with regard to varieties of matter. The many will have been reduced to the few.

The proofs of the physical reality of the entities discovered by means of the two analyses must necessarily be different. The chemist can actually produce the elementary constituents into which he has resolved a compound mass. No physicist or chemist can produce a single atom separated from all its fellows, and show that it possesses the elementary qualities he assigns to it. The cogency of the evidence for any suggested constitution of atoms must vary with the number of facts which the hypothesis that they possess that constitution explains.

Let us take, then, two steps in their proper order, and inquire, first, whether there is valid ground for believing that all matter is made up of discrete parts; and secondly, whether we can have any knowledge of the constitution or properties which those parts possess.

The Coarse-grainedness of Matter.

Matter in bulk appears to be continuous. Such substances as water or air appear to the ordinary observer to be perfectly uniform in all their properties and qualities, in all their parts.

The hasty conclusion that these bodies are really uniform is, nevertheless, unthinkable.

In the first place, the phenomena of diffusion afford conclusive proof that matter when apparently quiescent is in fact in a state of internal commotion. I need not recapitulate the familiar evidence to prove that gases and many liquids when placed in communication interpenetrate or diffuse into each other; or that air, in contact with a surface of water, gradually becomes laden with water vapour, while the atmospheric gases in turn mingle with the water. Such phenomena are not exhibited by liquids and gases alone, or by solids at high temperatures only. Sir W. Roberts-Austen has placed pieces of gold and lead in contact at a temperature of 18° C. After four years the gold had travelled into the lead to such an extent that not only were the two metals united, but, on analysis, appreciable quantities of the gold were detected even at a distance of more than 5 millimetres from the common surface, while within a distance of three-quarters of a millimetre from the surface gold had penetrated into the lead to the extent of 1 oz. 6 dwts. per ton, an amount which could have been profitably extracted.

Whether it is or is not possible to devise any other intelligible account of the cause of such phenomena, it is certain that a simple and adequate explanation is found in the hypothesis that matter consists of discrete parts in a state of motion, which can penetrate into the spaces between the corresponding parts of surrounding bodies.

The hypothesis thus framed is also the only one which affords a rational explanation of other simple and well-known facts. If matter is regarded as a continuous medium, the phenomena of expansion are unintelligible. There is, apparently, no limit to the expansion of matter, or, to fix our attention on one kind of matter, let us say to the expansion of a gas; but it is inconceivable that a continuous material which fills or is present in every part of a given space could also be present in every part of a space a million times as great. Such a statement might be made of a mathematical abstraction; it cannot be true of any real substance or thing. If, however, matter consists of discrete particles, separated from each other either by empty space or by something different from themselves, we can at once understand that expansion and contraction may be nothing more than the mutual separation or approach of these particles.

Again, no clear mental picture can be formed of the phenomena of heat unless we suppose that heat is a mode of motion. In the words of Rumford, it is "extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner the heat was excited and communicated in [his] experiment [on friction] except it be motion" (*Phil. Trans.*, 1798, p. 99). And if heat be motion there can be no doubt that it is the fundamental particles of matter which are moving. For the motion is not visible, is not motion of the body as a whole, while diffusion, which is a movement of matter, goes on more quickly as the temperature rises, thereby proving that the internal motions have become more rapid, which is exactly the result which would follow if these were the movements which constitute sensible heat.

Combining, then, the phenomena of diffusion, expansion, and heat, it is not too much to say that no hypotheses which make them intelligible have ever been framed other than those which are at the basis of the atomic theory.

Many other considerations also point to the same conclusion. Many years ago Lord Kelvin gave independent arguments, based on the properties of gases, on the constitution of the surfaces of liquids, and on the electric properties of metals, all of which indicate that matter is, to use his own phrase, coarse-grained—that it is not identical in constitution throughout, but that adjacent minute parts are distinguishable from each other by being either of different natures or in different states.

And here it is necessary to insist that all these fundamental proofs are independent of the nature of the particles or granules into which matter must be divided.

The particles, for instance, need not be different in kind from the medium which surrounds and separates them. It would suffice if they were what may be called singular parts of the medium itself, differing from the rest only in some peculiar state of internal motion or of distortion, or by being in some other way earmarked as distinct individuals. The view that the constitution of matter is atomic may and does receive support from theories in which definite assumptions are made as to the constitution of the atoms; but when, as is often the case, these assumptions introduce new and more recondite difficulties, it must be remembered that the fundamental hypothesis—that matter consists of discrete parts, capable of independent motions—is forced upon us by facts and arguments which are altogether independent of what the nature and properties of these separate parts may be.

As a matter of history, the two theories, which are not by any means mutually exclusive, that atoms are particles which can be treated as distinct in kind from the medium which surrounds them, and that they are parts of that medium existing in a special state, have both played a large part in the theoretical development of the atomic hypothesis. The atoms of Waterston, Clausius, and Maxwell were particles. The vortex-atoms of Lord Kelvin, and the strain-atoms (if I may call them so) suggested by Mr. Larmor, are states of a primary medium which constitutes a physical connection between them, and through which their mutual actions arise and are transmitted.

Properties of the Basis of Matter.

It is easy to show that, whichever alternative be adopted, we are dealing with something, whether we consider it under the guise of separate particles or of differentiated portions of the medium, which has properties different from those of matter in bulk.

For if the basis of matter had the same constitution as matter, the irregular heat movements could hardly be maintained either against the viscosity of the medium or the frittering away of energy of motion which would occur during the collisions between the particles. Thus, even in the case in which a hot body is prevented from losing heat to surrounding objects, its sensible heat should spontaneously decay by a process of self-cooling. No such phenomenon is known, and though on this, as on all other points, the limits of our knowledge are fixed by the uncertainty of experiment, we are compelled to admit that, to all appearance, the fundamental medium, if it exists, is unlike a material medium, in that it is non-viscous; and that the particles, if they exist, are so constituted that energy is not frittered away when they collide. In either case, we are dealing with something different from matter itself in the sense that, though it is the basis of matter, it is not identical in all its properties with matter.

The idea therefore that entities exist possessing properties different from those of matter in bulk is not introduced at the end of a long and recondite investigation to explain facts with which none but experts are acquainted. It is forced upon us at the very threshold of our study of Nature. Either the properties of matter in bulk cannot be referred to any simpler structure, or that simpler structure must have properties different from those of matter in bulk as we directly knew it—properties which can only be inferred from the results which they produce.

No *a priori* argument against the possibility of our discovering the existence of quasi-material substances, which are nevertheless different from matter, can prove the negative proposition that such substances cannot exist. It is not a self-evident truth that no substance other than ordinary matter can have an existence as real as that of matter itself. It is not axiomatic that matter cannot be composed of parts whose properties are different from those of the whole. To assert that even if such substances and such parts exist no evidence however cogent could convince us of their existence is to beg the whole question at issue; to decide the cause before it has been heard.

We must therefore adhere to the standpoint adopted by most scientific men, viz., that the question of the existence of ultra-physical entities, such as atoms and the ether, is to be settled by the evidence, and must not be ruled out as inadmissible on *a priori* grounds.

On the other hand, it is impossible to deny that, if the mere entry on the search for the concealed causes of physical phenomena is not a trespass on ground we have no right to explore, it is at all events the beginning of a dangerous journey.

The wraiths of phlogiston, caloric, luminiferous corpuscles, and a crowd of other phantoms haunt the investigator, and as the grim host vanishes into nothingness he cannot but wonder if his own conceptions of atoms and of the ether

> "shall dissolve,
> And, like this insubstantial pageant faded,
> Leave not a wrack behind."

But though science, like Bunyan's hero, has sometimes had to pass through the "Valley of Humiliation," the spectres which meet it there are not really dangerous if they are boldly faced. The facts that mistakes have been made, that theories have been propounded, and for a time accepted, which later investigations have disproved, do not necessarily discredit the method adopted. In scientific theories, as in the world around us, there is a survival of the fittest, and Dr. James Ward's unsympathetic account of the blunders of those whose work, after all, has shed glory on the nineteenth century, might *mutatis mutandis* stand for a description of the history of the advance of civilisation. "The story of the progress so far," he tells us, "is briefly this: Divergence between theory and fact one part of the way, the wreckage of abandoned fictions for the rest, and an unattainable goal of phenomenal nihilism and ultra-physical mechanism beyond" ("Naturalism and Agnosticism," vol. i. p. 153).

"The path of progress," says Prof. Karl Pearson, "is strewn with the wreck of nations. Traces are everywhere to be seen of the hecatombs of inferior races, and of victims who found not the narrow way to the greater perfection. Yet these dead peoples are, in very truth, the stepping-stones on which mankind has arisen to the higher intellectual and deeper emotional life of to-day" ("National Life from the Standpoint of Science," p. 62).

It is only necessary to add that the progress of society is directed towards an unattainable goal of universal contentment, to make the parallel complete.

And so, in the one case as in the other, we may leave "the dead to bury their dead." The question before us is not whether we too may not be trusting to false ideas, erroneous experiments, evanescent theories. No doubt we are; but, without making an insolent claim to be better than our fathers, we may fairly contend that, amid much that is uncertain and temporary, some of the fundamental conceptions, some of the root-ideas of science, are so grounded on reason and fact that we cannot but regard them as an aspect of the very truth.

Enough has, perhaps, now been said on this point for my immediate purpose. The argument as to the constitution of matter could be developed further in the manner I have hitherto adopted, viz. by series of propositions, the proof of each of which is based upon a few crucial phenomena. In particular, if matter is divided into moving granules or particles, the phenomenon of cohesion proves that there must be mutual actions between them analogous to those which take place between large masses of matter, and which we ascribe to force, thereby indicating the regular, unvarying operation of active machinery which we have not yet the means of adequately understanding. For the moment, I do not wish to extend the line of reasoning that has been followed. My main object is to show that the notion of the existence of ultra-physical entities and the leading outlines of the atomic theory are forced upon us at the beginning of our study of Nature, not only by *a priori* considerations, but in the attempt to comprehend the results of even the simplest observation. These outlines cannot be effaced by the difficulties which undoubtedly arise in filling up the picture. The cogency of the proof that matter is coarse-grained is in no way affected by the fact that we may have grave doubts as to the nature of the granules. Nay, it is of the first importance to recognise that, though the fundamental assumptions of the atomic theory receive overwhelming support from a number of more detailed arguments, they are themselves almost of the nature of axioms, in that the simplest phenomena are unintelligible if they are abandoned.

The Range of the Atomic Theory.

It would be most unfair, however, to the atomic theory to represent it as depending on one line of reasoning only, or to treat its evidence as bounded by the very general propositions I have discussed.

It is true that as the range of the theory is extended the fundamental conception that matter is granular must be expanded and filled in by supplementary hypotheses as to the constitution of the granules. It may also be admitted that no complete or wholly satisfactory description of that constitution can as yet be given; that perfection has not yet been attained here or in any other branch of science; but the number of facts which can be accounted for by the theory is very large compared with the number of additional hypotheses which are introduced; and the cumulative weight of the additional evidence obtained by the study of details is such as to add greatly to the strength of the conviction that, in its leading outlines, the theory is true.

It was originally suggested by the facts of chemistry, and though, as we have seen, a school of chemists now thrusts it into the background, it is none the less true, in the words of Dr. Thorpe, that "every great advance in chemical knowledge during the last ninety years finds its interpretation in [Dalton's] theory" ("Essays on Historical Chemistry," 1894, p. 368).

The principal mechanical and thermal properties of gases have been explained, and in large part discovered, by the aid of the atomic theory; and, though there are outstanding difficulties, they are, for the most part, related to the nature of the atoms and molecules, and do not affect the question as to whether they exist.

The fact that different kinds of light all travel at the same speed in interplanetary space, while they move at different rates in matter, is explained if matter is coarse-grained. But to attempt to sum up all this evidence would be to recite a text-book on physics. It must suffice to say that it is enormous in extent and varied in character, and that the atomic theory imparts a unity to all the physical sciences which has been attained in no other way.

I must, however, give a couple of instances of the wonderful success which has been achieved in the explanation of physical phenomena by the theory we are considering, and I select them because they are in harmony with the line of argument I have been pursuing.

When a piece of iron is magnetised, its behaviour is different according as the magnetic force applied to it is weak, moderate, or strong. When a certain limit is passed, the iron behaves as a non-magnetic substance to all further additions of magnetic force. With strong forces it does and with very weak forces it does not remain magnetised when the force ceases to act. Prof. Ewing has imitated all the minute details of these complicated properties by an arrangement of small isolated compass needles to represent the molecules. It may fairly be said that as far as this particular set of phenomena is concerned a most instructive working model based on the molecular theory has not only been imagined but constructed.

The next illustration is no less striking. We may liken a crowd of molecules to a fog; but while the fog is admitted by everybody to be made up of separate globules of water, the critics of scientific method are sometimes apt to regard the molecules as mere fictions of the imagination. If, however, we could throw the molecules of a highly rarefied gas into such a state that vapour condensed on them, so that each became the centre of a water-drop, till the host of invisible molecules was, as it were, magnified by accretion into a visible mist, surely no stronger proof of their reality could be desired. Yet there is every reason to believe that something very like this has been accomplished by Mr. C. T. R. Wilson and Prof. J. J. Thomson.

It is known that it is comparatively difficult to produce a fog in damp air if the mixture consists of air and water-vapour alone. The presence of particles of very fine dust facilitates the process. It is evident that the vapour condenses on the dust particles, and that a nucleus of some kind is necessary on which each drop may form. But electrified particles also act as nuclei; for if a highly charged body from which electricity is escaping be placed near a steam jet, the steam condenses; and a cloud is also formed in dust-free air more easily than would otherwise be the case if electricity is discharged into it.

Again, according to accepted theory, when a current of electricity flows through a gas, some of the atoms are divided into parts which carry positive and negative charges as they move in opposite directions, and unless this breaking-up occurs a gas does not conduct electricity. But a gas can be made a conductor merely by allowing the Röntgen rays or the radiation given off by uranium to fall upon it. A careful study of the facts shows that it is probable that some of the atoms have been broken up by the radiation, and that their oppositely electrified parts are scattered among their unaltered fellows. Such a gas is said to be ionised.

Thus by these two distinct lines of argument we come to the conclusions:—1st, that the presence of electrified particles promotes the formation of mist, and 2nd, that in an ionised gas such electrified particles are provided by the breaking-up of atoms.

The two conclusions will mutually support each other if it can be shown that a mist is easily formed in ionised air. This was tested by Mr. Wilson, who showed that in such air mist is formed as though nuclei were present, and thus in the cloud we have visible evidence of the presence of the divided atoms. If, then, we cannot handle the individual molecules, we have at least some reason to believe that a method is known of seizing individuals, or parts of individuals, which are in a special state, and of wrapping other matter round them till each one is the centre of a discrete particle of a visible fog.

I have purposely chosen this illustration, because the explanation is based on a theory—that of ionisation—which is at present subjected to hostile criticism. It assumes that an electrical current is nothing more than the movement of charges of electricity. But magnets placed near to an electric current tend to set themselves at right angles to its direction; a fact on which the construction of telegraphic instruments is based. Hence if the theory be true, a similar effect ought to be produced by a moving charge of electricity. This experiment was tried many years ago in the laboratory of Helmholtz by Rowland, who caused a charged disc to spin rapidly near a magnet. The result was in accord with the theory; the magnet moved as though acted upon by an electric current. Of late, however, M. Crémieu has investigated the matter afresh, and has obtained results which, according to his interpretation, were inconsistent with that of Rowland.

M. Crémieu's results are already the subject of controversy,[1] and are, I believe, likely to be discussed in the Section of Physics. This is not the occasion to enter upon a critical discussion of the question at issue, and I refer to it only to point out that though, if M. Crémieu's result were upheld, our views as to electricity would have to be modified, the foundations of the atomic theory would not be shaken.

It is, however, from the theory of ions that the most far-reaching speculations of science have recently received unexpected support. The dream that matter of all kinds will some day be proved to be fundamentally the same has survived many shocks. The opinion is consistent with the great generalisation that the properties of elements are a periodic function of their atomic weights. Sir Norman Lockyer has long been a prominent exponent of the view that the spectra of the stars indicate the reduction of our so-called elements to simpler forms, and now Prof. J. J. Thomson believes that we can break off from an atom a part, the mass of which is not more than one-thousandth of the whole, and that these corpuscles, as he has named them, are the carriers of the negative charge in an electric current. If atoms are thus complex, not only is the *a priori* probability increased that the different structures which we call elements may all be built of similar bricks, but the discovery by Lenard

[1] See *Phil. Mag.*, July 1901, p. 144; and *Johns Hopkins University Circulars*, xx. No. 152, May–June 1901, p. 78.

that the ease with which the corpuscles penetrate different bodies depends only on the density of the obstacles, and not on their chemical constitution, is held by Prof. Thomson to be "a strong confirmation of the view that the atoms of the elementary substances are made up of simpler parts, all of which are alike."[1] On the present occasion, however, we are occupied rather with the foundations than with these ultimate ramifications of the atomic theory; and having shown how wide its range is, I must, to a certain extent, retrace my steps and return to the main line of my argument.

The Properties of Atoms and Molecules.

For if it be granted that the evidence that matter is coarse-grained and is formed of separate atoms and molecules is too strong to be resisted, it may still be contended that we can know little or nothing of the sizes and properties of the molecules.

It must be admitted that, though the fundamental postulates are always the same, different aspects of the theory, which have not in all cases been successfully combined, have to be developed when it is applied to different problems; but in spite of thi there is little doubt that we have some fairly accurate knowledge of molecular motions and magnitudes.

If a liquid is stretched into a very thin film, such as a soap-bubble, we should expect indications of a change in its properties when the thickness of the film is not a very large multiple of the average distance between two neighbouring molecules. In 1890 Sohncke (*Wied. Ann.*, 1890, xl. pp. 345–355) detected evidence of such a change in films of the average thickness of 106 millionths of a millimetre ($\mu\mu$), and quite recently Rudolph Weber found it in an oil-film when the thickness was 115 $\mu\mu$ (*Annalen der Physik*, 1901, iv. pp. 706–721).

Taking the mean of these numbers and combining the results of different variants of the theory, we may conclude that a film should become unstable and tend to rupture spontaneously somewhere between the thicknesses of 110 and 55 $\mu\mu$, and Prof. Reinold and I found by experiment that this instability is actually exhibited between the thicknesses of 96 and 45 $\mu\mu$ (*Phil. Trans.*, 1893, 184, pp. 505–529). There can therefore be little doubt that the first approach to molecular magnitudes is signalled when the thickness of a film is somewhat less than 100 $\mu\mu$, or 4 millionths of an inch.

Thirteen years ago I had the honour of laying before the Chemical Society a *résumé* of what was then known on these subjects (*Chem. Soc. Trans.*, liii., March 1888, pp. 222–262), and I must refer to that lecture or to the most recent edition of O. E. Meyer's work on the kinetic theory of gases ("Kinetic Theory of Gases," O. E. Meyer, 1899; translated by R. E. Baynes) for the evidence that various independent lines of argument enable us to estimate quantities very much less than 4 millionths of an inch, which is perhaps from 500 to 1000 times greater than the magnitude which, in the present state of our knowledge, we can best describe as the diameter of a molecule.

Confining our attention, however, to the larger quantities, I will give one example to show how strong is the cumulative force of the evidence as to our knowledge of the magnitudes of molecular quantities.

We have every reason to believe that though the molecules in a gas frequently collide with each other, yet in the case of the more perfect gases the time occupied in collisions is small compared with that in which each molecule travels undisturbed by its fellows. The average distance travelled between two successive encounters is called the mean free path, and, for the reason just given, the question of the magnitude of this distance can be attacked without any precise knowledge of what a molecule is, or of what happens during an encounter.

Thus the mean free path can be determined, by the aid of the theory, either from the viscosity of the gas or from the thermal conductivity. Using figures given in the latest work on the subject (Meyer's "Kinetic Theory of Gases"; see above), and dealing with one gas only, as a fair sample of the rest, the lengths of the mean free path of hydrogen as determined by these two independent methods differ only by about 3 per cent. Further, the mean of the values which I gave in the lecture already referred to differed only by about 6 per cent. from the best modern result, so that no great change has been introduced during the last thirteen years.

[1] For the most recent account of this subject see an article on "Bodies Smaller than Atoms," by Prof. J. J. Thomson in the *Popular Science Monthly* (The Science Press), August 1901.

It may, however, be argued that these concordant values are all obtained by means of the same theory, and that a common error may affect them all. In particular, some critics have of late been inclined to discredit the atomic theory by pointing out that the strong statements which have sometimes been made as to the equality, among themselves, of atoms or molecules of the same kind may not be justified, as the equality may be that of averages only, and be consistent with a considerable variation in the sizes of individuals.

Allowing this argument more weight than it perhaps deserves, it is easy to show that it cannot affect seriously our knowledge of the length of the mean free path.

Prof. George Darwin (*Phil. Trans.*, 180) has handled the problem of a mixture of unequal spherical bodies in the particular case in which the sizes are distributed according to the law of errors, which would involve far greater inequalities than can occur among atoms. Without discussing the precise details of his problem, it is sufficient to say that in the case considered by him the length of the mean free path is 7/11 of what it would be if the particles were equal. Hence, were the inequalities of atoms as great as in this extreme case, the reduction of the mean free path in hydrogen could only be from 185 to 119 $\mu\mu$; but they must be far less, and therefore the error, if any, due to this cause could not approach this amount. It is probably inappreciable.

Such examples might be multiplied, but the one I have selected is perhaps sufficient to illustrate my point, viz., that considerable and fairly accurate knowledge can be obtained as to molecular quantities by the aid of theories the details of which are provisional, and are admittedly capable of improvement.

Is the Model Unique?

But the argument that a correct result may sometimes be obtained by reasoning on imperfect hypotheses raises the question as to whether another danger may not be imminent. To be satisfactory, our model of Nature must be unique, and it must be impossible to imagine any other which agrees equally well with the facts of experiment. If a large number of hypotheses could be framed with equal claims to validity, that fact would alone raise grave doubts as to whether it were possible to distinguish between the true and the false. Thus Prof. Poincaré has shown that an infinite number of dynamical explanations can be found for any phenomenon which satisfies certain conditions. But though this consideration warns us against the too ready acceptance of explanations of isolated phenomena, it has no weight against a theory which embraces so vast a number of facts as those included by the atomic theory. It does not follow that, because a number of solutions are all formally dynamical, they are therefore all equally admissible. The pressure of a gas may be explained as the result of a shower of blows delivered by molecules, or by a repulsion between the various parts of a continuous medium. Both solutions are expressed in dynamical language; but one is, and the other is not, compatible with the observed phenomena of expansion. The atomic theory must hold the field until another can be found which is not inferior as an explanation of the fundamental difficulties as to the constitution of matter, and is, at the same time, not less comprehensive.

On the whole, then, the question as to whether we are attempting to solve a problem which has an infinite number of solutions may be put aside until one solution has been found which is satisfactory in all its details. We are in a sufficient difficulty about that to make the rivalry of a second of the same type very improbable.

The Phenomena of Life.

But it may be asked—nay, it has been asked—may not the type of our theories be radically changed? If this question does not merely imply a certain distrust in our own powers of reasoning, it should be supported by some indication of the kind of change which is conceivable.

Perhaps the chief objection which can be brought against physical theories is that they deal only with the inanimate side of Nature, and largely ignore the phenomena of life. It is therefore in this direction, if in any, that a change of type may be expected. I do not propose to enter at length upon so difficult a question, but, however we may explain or explain away the characteristics of life, the argument for the truth of the atomic theory would only be affected if it could be shown that living matter does not possess the thermal and mechanical properties, to explain which the atomic theory has been framed. This is so notoriously not the case that there is the gravest doubt whether life can in any way interfere with the action within the organism of the laws of matter in bulk belonging to the domain of mechanics, physics, and chemistry.

Probably the most cautious opinion that could now be expressed on this question is that, in spite of some outstanding difficulties which have recently given rise to what is called Neo-vitalism, there is no conclusive evidence that living matter can suspend or modify any of the natural laws which would affect it if it were to cease to live. It is possible that though subject to these laws the organism while living may be able to employ, or even to direct, their action within itself for its own benefit, just as it unquestionably does make use of the processes of external nature for its own purposes; but if this be so, the seat of the controlling influence is so withdrawn from view that, on the one hand, its very existence may be denied, while, on the other hand, Prof. Haeckel, following Vogt, has recently asserted that "matter and ether are not dead, and only moved by extrinsic force; but they are endowed with sensation and will; they experience an inclination for condensation, a dislike for strain; they strive after the one and struggle against the other" ("Riddle of the Universe," English translation, 1900, p. 380).

But neither unproved assertions of this kind nor the more refined attempts that have been made by others to bring the phenomena of life and of dead matter under a common formula touch the evidence for the atomic theory. The question as to whether matter consists of elements capable of independent motion is prior to and independent of the further questions as to what these elements are, and whether they are alive or dead.

The physicist, if he keeps to his business, asserts, as the bases of the atomic theory, nothing more than that he who declines to admit that matter consists of separate moving parts must regard many of the simplest phenomena as irreconcilable and unintelligible, in spite of the fact that means of reconciling them are known to everybody, in spite of the fact that the reconciling theory gives a general correlation of an enormous number of phenomena in every branch of science, and that the outstanding difficulties are connected, not so much with the fundamental hypotheses that matter is composed of distinguishable entities which are capable of separate motions as with the much more difficult problem of what these entities are.

On these grounds the physicist may believe that, though he cannot handle or see them, the atoms and molecules are as real as the ice crystals in a cirrus cloud which he cannot reach; as real as the unseen members of a meteoric swarm whose death-glow is lost in the sunshine, or which sweep past us, unentangled, in the night.

If the confidence that his methods are weapons with which he can fight his way to the truth were taken from the scientific explorer, the paralysis which overcomes those who believe that they are engaged in a hopeless task would fall upon him.

Physiology has specially flourished since physiologists have believed that it is possible to master the physics and chemistry of the framework of living things, and since they have abandoned the attitude of those who placed in the foreground the doctrine of the vital force. To supporters of that doctrine the principle of life was not a hidden directing power which could perhaps whisper an order that the flood-gates of reservoirs of energy should now be opened and now closed, and could, at the most, work only under immutable conditions to which the living and the dead must alike submit. On the contrary, their vital force pervaded the organism in all its parts. It was an active and energetic opponent of the laws of physics and chemistry. It maintained its own existence not by obeying but by defying them; and though destined to be finally overcome in the separate campaigns of which each individual living creature is the scene, yet like some guerilla chieftain it was defeated here only to reappear there with unabated confidence and apparently undiminished force.

This attitude of mind checked the advance of knowledge. Difficulty could be evaded by a verbal formula of explanation which in fact explained nothing. If the mechanical, or physical, or chemical causes of a phenomenon did not lie obviously upon the surface, the investigator was tempted to forego the toil of searching for them below; it was easier to say that the vital force was the cause of the discrepancy, and that it was hopeless to attempt to account for the action of a principle which was incomprehensible in its nature.

For the physicist the danger is no less serious, though it lies in a somewhat different direction. At present he is checked in his theories by the necessity of making them agree with a comparatively small number of fundamental hypotheses. If this check were removed, his fancy might run riot in the wildest speculations, which would be held to be legitimate if only they led to formulæ in harmony with facts. But the very habit of regarding the end as everything, and the means by which it was attained as unimportant, would prevent the discovery of those fragments of truth which can only be uncovered by the painful process of trying to make inconsistent theories agree, and using all facts, however remote, as the tests of our central generalisation.

"Science," said Helmholtz, "Science, whose very object it it is to comprehend Nature, must start with the assumption that Nature is comprehensible." And again, "The first principle of the investigator of Nature is to assume that Nature is intelligible to us, since otherwise it would be foolish to attempt the investigation at all." These axioms do not assume that all the secrets of the universe will ultimately be laid bare, but that a search for them is hopeless if we undertake the quest with the conviction that it will be in vain. As applied to life, they do not deny that in living matter something may be hidden which neither physics nor chemistry can explain, but they assert that theaction of physical and chemical forces in living bodies can never be understood, if at every difficulty and at every check in our investigations we desist from further attempts in the belief that the laws of physics and chemistry have been interfered with by an incomprehensible vital force. As applied to physics and chemistry, they do not mean that all the phenomena of life and death will ultimately be included in some simple and self-sufficing mechanical theory: they do mean that we are not to sit down contented with paradoxes such as that the same thing can fill both a large space and a little one; that matter can act where it is not, and the like, if by some reasonable hypothesis, capable of being tested by experiment, we can avoid the acceptance of these absurdities. Something will have been gained if the more obvious difficulties are removed, even if we have to admit that in the background there is much that we cannot grasp.

The Limits of Physical Theories.

And this brings me to my last point. It is a mistake to treat physical theories in general, and the atomic theory in particular, as though they were parts of a scheme which has failed if it leaves anything unexplained, which must be carried on indefinitely on exactly the same principles, whether the ultimate results are, or are not, repugnant to common-sense.

Physical theories begin at the surface with phenomena which directly affect our senses. When they are used in the attempt to penetrate deeper into the secrets of Nature, it is more than probable that they will meet with insuperable barriers, but this fact does not demonstrate that the fundamental assumptions are false, and the question as to whether any particular obstacle will be for ever insuperable can rarely be answered with certainty.

Those who belittle the ideas which have of late governed the advance of scientific theory too often assume that there is no alternative between the opposing assertions that atoms and the ether are mere figments of the scientific imagination, or that, on the other hand, a mechanical theory of the atoms and of the ether, which is now confessedly imperfect, would, if it could be perfected, give us a full and adequate representation of the underlying realities.

For my own part I believe that there is a *via media.*

A man peering into a darkened room, and describing what he thinks he sees, may be right as to the general outline of the objects he discerns, wrong as to their nature and their precise forms. In his description fact and fancy may be blended, and it may be difficult to say where the one ends and the other begins; but even the fancies will not be worthless if they are based on a fragment of truth, which will prevent the explorer from walking into a looking-glass or stumbling over the furniture. He who saw "men as trees walking" had at least a perception of the fundamental fact that something was in motion around him.

And so, at the beginning of the twentieth century, we are neither forced to abandon the claim to have penetrated below the surface of Nature, nor have we, with all our searching, torn the veil of mystery from the world around us.

The range of our speculations is limited both in space and time: in space, for we have no right to claim, as is sometimes done, a knowledge of the "infinite universe"; in time, for the cumulative effects of actions which might pass undetected in the short span of years of which we have knowledge, may, if continued long enough, modify our most profound generalisations. If some such theory as the vortex-atom theory were true, the faintest trace of viscosity in the primordial medium would ultimately destroy matter of every kind. It is thus a duty to state what we believe we know in the most cautious terms, but it is equally a duty not to yield to mere vague doubts as to whether we can know anything.

If no other conception of matter is possible than that it consists of distinct physical units—and no other conception has been formulated which does not blur what are otherwise clear and definite outlines—if it is certain, as it is, that vibrations travel through space which cannot be propagated by matter, the two foundations of physical theory are well and truly laid. It may be granted that we have not yet framed a consistent image either of the nature of the atoms or of the ether in which they exist; but I have tried to show that in spite of the tentative nature of some of our theories, in spite of many outstanding difficulties, the atomic theory unifies so many facts, simplifies so much that is complicated, that we have a right to insist—at all events till an equally intelligible rival hypothesis is produced—that the main structure of our theory is true; that atoms are not merely helps to puzzled mathematicians, but physical realities.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY MAJOR P. A. MACMAHON, D.Sc., F.R.S., PRESIDENT OF THE SECTION.

DURING the seventy meetings of the Association a pure mathematician has been president of Section A on ten or a dozen occasions. A theme taken by many has been a defence of the study of pure mathematics. I take Cayley's view expressed before the whole Association at Southport in 1883, that no defence is necessary, but were it otherwise, I feel that nothing need be added to the eloquent words of Sylvester in 1869 and of Forsyth in 1897. I intend, therefore, to make some remarks on several matters which may be interesting to the Section even at the risk of being considered unduly desultory.

Before commencing I must remark that during the twelve months that have elapsed since the Bradford Meeting we have lost several great men whose lives were devoted to the subjects of this Section. Hermite, the veteran mathematician of France, has left behind him a splendid record of purely scientific work. His name will be always connected with the herculean achievement of solving the general quintic equation by means of elliptic modular functions. Other work, if less striking, is equally of the highest order, and his treatise "Cours d'Analyse" is a model of style. Of Fitzgerald of Dublin it is not easy to speak in this room without emotion. For many years he was the life and soul of this Section. His enthusiasm in regard to all branches of molecular physics, the force and profundity of his speech, the vigour of his advocacy of particular theories, the acute thinking which enabled him to formulate desiderata, his warm interest in the work of others, and the unselfish aid he was so willing to give, are fresh in our remembrance. Rowland was in the forefront of the ranks of physicists. His death at a comparatively early age terminates the important series of discoveries which were proclaimed from his laboratory in the Johns Hopkins University at Baltimore. In Viriamu Jones we have lost an assiduous worker at physics whose valuable contributions to knowledge indicated his power to do much more for science. In Tait, Scotland possessed a powerful and original investigator. The extent and variety of his papers are alike remarkable, and in his collected works there exists an imperishable monument to his fame.

It is interesting, in this the first year of the new century, to take a rapid glance at the position that mathematicians of this country held amongst mathematicians a hundred years ago. During the greater part of the eighteenth century the study of mathematics in England, Scotland and Ireland had been at a very low ebb. Whereas in 1801 on the Continent there were the leaders Lagrange, Laplace and Legendre, and of rising men, Fourier, Ampère, Poisson and Gauss, we could only claim Thomas Young and Ivory as men who were doing notable work in research. Amongst schoolboys of various ages we note Fresnel, Bessel, Cauchy, Chasles, Lamé, Möbius, v. Staudt and Steiner on the Continent, and Babbage, Peacock, John Herschel, Henry Parr Hamilton and George Green in this country. It was not, indeed, till about 1845, or a little later, that we could point to the great names of William Rowan Hamilton, MacCullagh, Adams, Boole, Salmon, Stokes, Sylvester, Cayley, William Thomson, H. J. S. Smith and Clerk Maxwell as adequate representatives of mathematical science. It is worthy of note that this date, 1845, marks also the year of the dissolution of a very interesting society, the Mathematical Society of Spitalfields; and I would like to pause a moment, and, if I may say so, rescue it from the oblivion which seems to threaten it. In 1801 it was already a venerable institution, having been founded by Joseph Middleton, a writer of mathematical text-books, in 1717.[1] The members of the Society at the beginning were for the most part silk-weavers of French extraction; it was little more than a working man's club, at which questions of mathematics and natural philosophy were discussed every Saturday evening. The number of members was limited to the "square of seven," but later it was increased to the "square of eight," and later still to the "square of nine." In 1725 the place of meeting was changed from the Monmouth's Head to the White Horse in Wheeler Street, and in 1735 to the Ben Jonson's Head in Pelham Street. The subscription was six-and-sixpence a quarter, or sixpence a week, and entrance was gained by production of a metal ticket, which had the proposition of Pythagoras engraved on one side and a sighted quadrant with level on the other. The funds, largely augmented by an elaborate system of fines, were chiefly used for the purchase of books and philosophical apparatus. A president, treasurer, inspector of instruments, and secretary were appointed annually, and there were, besides, four stewards, six auditors and six trustees. By the constitution of the Society it was the duty of every member, if he were asked any mathematical or philosophical question by another member, to instruct him to the best of his ability. It was the custom for each member in rotation to lecture or perform experiments on each evening of meeting. There was a fine of half-a-crown for introducing controverted points of divinity or politics. The members dined together twice annually, viz. on the second Friday in January in London in commemoration of the birth of Sir Isaac Newton (this feast frequently took place at the Black Swan, Brown's Lane, Spitalfields), and on the second Friday in July "at a convenient distance in the country in commemoration of the birth of the founder." The second dinner frequently fell through because the members could not agree as to the locality. It was found necessary to introduce a rule fining members sixpence for letting off fireworks in the place of meeting. Every member present was entitled to a pint of beer at the common expense, and, further, every five members were entitled to call for a quart for consumption at the meeting. Such were some of the quaint regulations in force when about the year 1750 the Society moved to larger apartments in Crispin Street, where it remained without interruption till 1843. It appears from the old minute books that about the year 1750 the Society absorbed a small mathematical society which used to meet at the Black Swan, Brown's Lane, above mentioned, and that in 1783 an ancient historical society was also incorporated with it. By the year 1800 the class of the members had become improved, and we find some well-known names, such as Dolland, Simpson, Saunderson, Crossley, Paroissen and Gompertz. At the time lectures were given in all branches of science by the members in the Society's rooms, which on these occasions were open to the public on payment of one shilling. The arrangements for the session 1822–23 included lectures in mechanics, hydrostatics and hydraulics, pneumatics, optics, astronomy, chemistry, electricity, galvanism, magnetism and botany, illustrated by experiments. On account of these lectures the Society had to fight an action-at-law, and although the case was won, its slender resources were crippled for many years. In 1827 Benjamin Gompertz, F.R.S., succeeded to the presidency on the death of the Rev. George Paroissen. From the year 1830 onwards the membership gradually declined and the financial outlook became serious. In 1843 there was a crisis; the Society left Crispin Street for cheaper rooms at 9 Devonshire Street, Bishopsgate Street, and finally, in 1845, after a futile negotiation with the London Institution, it was taken over by the Royal Astronomical Society, which had been founded in 1821. The library and documents were accepted and the few surviving members were made life members of the Astronomical Society without payment. So perished this curious old institution; it had amassed a really valuable library containing books on all branches of science. The Astronomical Society has retained the greater part, but some have found their way to the libraries of the Chemical and other societies. An inspection of the documents establishes that it was mainly a society devoted to physics, chemistry and natural history. It had an extensive museum of curiosities and specimens of natural history, presented by individual members, which seems to have disappeared when the rooms in Crispin Street were vacated. It seems a pity that more effort was not made to keep the old institution alive. The fact is that at that date the Royal Society had no sympathy with special societies and did all in its power to discourage them. The Astronomical Society was only formed in 1821 in the teeth of the opposition of the Royal Society.

[1] Its first place of meeting was the Monmouth's Head, Monmouth Street, Spitalfields. This street has long disappeared. From a map of London of 1746 it appears to have run parallel to the present Brick Lane and to have orresponded to the present Wilks Street.

Reverting now to the date 1845, it may be said that from this period to 1866 much good work emanated from this country, but no Mathematical Society existed in London. At the latter date the present Society was formed, with De Morgan as its first president. Gompertz was an original member, and the only person who belonged to both the old and new societies. The thirty-three volumes of *Proceedings* that have appeared give a fair indication of the nature of the mathematical work that has issued from the pens of our countrymen. All will admit that it is the duty of any one engaged in a particular line of research to keep himself abreast of discoveries, inventions, methods and ideas, which are being brought forward in that line in his own and other countries. In pure science this is easier of accomplishment by the individual worker than in the case of applied science. In pure mathematics the stately edifice of the Theory of Functions has, during the latter part of the century which has expired, been slowly rising from its foundations on the continent of Europe. It had reached a considerable height and presented an imposing appearance before it attracted more than superficial notice in this country and in America. It is satisfactory to note that during recent years much of the leeway has been made up. English-speaking mathematicians have introduced the first notions into elementary text-books; they have written advanced treatises on the whole subject; they have encouraged the younger men to attend courses of lectures in foreign universities; so that to-day the best students in our universities can attend courses at home given by competent persons, and have the opportunity of acquiring adequate knowledge, and of themselves contributing to the general advance. The Theory of Functions, being concerned with the functions that satisfy differential equations, has attracted particularly the attention of those whose bent seemed to be towards applied mathematics and mathematical physics, and there is no doubt, in analogy with the work of Poincaré in celestial dynamics, those sciences will ultimately derive great benefit from the new study. If, on the other hand, one were asked to specify a department of pure mathematics which has been treated somewhat coldly in this country during the last quarter of the last century, one could point to geometry in general, and to pure geometry, descriptive geometry and the theory of surfaces in particular. This may doubtless be explained by the circumstance that, at the present time, the theory of differential equations and the problems that present themselves in their discussion are of such commanding importance from the point of view of the general advance of mathematical science that those subjects naturally prove to be most attractive.

As regards organisation and cooperation in mathematics, Germany, I believe, stands first. The custom of offering prizes for the solutions of definite problems which are necessary to the general advance obtains more in Germany and in France than here, where, I believe, the Adams Prize stands alone. The idea has an indirect value in pointing out some of the more pressing desiderata to young and enthusiastic students, and a direct importance in frequently, as it proves, producing remarkable dissertations on the proposed questions. The field is so vast that any comprehensive scheme of cooperation is scarcely possible, though much more might be done with advantage.

If we turn our eyes to the world of astronomy we find there a grand scheme of cooperation which other departments may indeed envy. The gravitation formula has been recognised from the time of Newton as ruling the dynamics of the heavens, and the exact agreement of the facts derived from observation with the simple theory has established astronomy as the most exact of all the departments of applied science. Men who devote themselves to science are actuated either by a pure love of truth or because they desire to apply natural knowledge to the benefit of mankind. Astronomers belong, as a rule, to the first category, which, it must be admitted, is the more purely scientific. We not only find international cooperation in systematically mapping the universe of stars and keeping all portions of the universe under constant observation, but also when a particular object in the heavens presents itself under circumstances of peculiar interest or importance, the observatories of the world combine to ascertain the facts in a manner which is truly remarkable. As an illustration, I will instance the tiny planet Eros discovered a few years ago by De Witt. Recently the planet was in opposition and more favourably situated for observation than it will be again for thirty years. It was determined, at a conference held in Paris in July 1900, that combined work should be undertaken by no fewer than fifty observatories in all parts of the world. Beyond the fixing of the elements of the mean motion and of the perturbations of orbit due to the major planets, the principal object in view is the more accurate determination of solar parallax. To my mind this concert of the world, this cosmopolitan association of fine intellects, fine instruments, and the best known methods, is a deeply impressive spectacle and a grand example of an ideal scientific spirit. Other sciences are not so favourably circumstanced as is astronomy for work of a similar kind undertaken in a similar spirit. If in comparison they appear to be in a chaotic state, the reason in part must be sought for in conditions inherent to their study, which make combined work more difficult, and the results of such combined work as there is less striking to spectators. Still, the illustration I have given is a useful object-lesson to all men of science, and may encourage those who have the ability and the opportunity to make strenuous efforts to further progress by bringing the work of many to a single focus.

In pure science we look for a free interchange of ideas, but in applied physics the case is otherwise, owing to the fact that the commercial spirit largely enters into them. In a recent address, Prof. Perry has stated that the standard of knowledge in electrical engineering in this country is not as high as it is elsewhere, and all men of science and many men in the street know that he is right. This is a serious state of affairs, to which the members of this Section cannot be in any sense indifferent. We cannot urge that it is a matter with which another Section of the Association is concerned to a larger degree. It is our duty to take an active, and not merely passive attitude towards this serious blot on the page of applied science in England. For this many reasons might be given, but it is sufficient to instance one, and to state that neglect of electrical engineering has a baneful effect upon research in pure science in this country. It hinders investigations in pure physics by veiling from observation new phenomena which arise naturally, and by putting out of our reach means of experimenting with new combinations on a large scale. Prof. Perry has assigned several reasons for the present *impasse*, viz., a want of knowledge of mathematics on the part of the rising generation of engineers; the bad teaching of mathematics, and antiquated methods of education generally; want of recognition of the fact that engineering is not on stereotyped lines, but, in its electrical aspect, is advancing at a prodigious rate; municipal procrastination, and so on. He confesses, moreover, that he does not see his way out of the difficulty, and is evidently in a condition of gloomy apprehension.

It is, I think, undoubted that science has been neglected in this country, and that we are reaping as we have sowed. The importance of science teaching in secondary schools has been overlooked. Those concerned in our industries have not seen the advantage of treating their workshops and manufactories as laboratories of research. The Government has given too meagre an endowment to scientific institutions, and has failed to adequately encourage scientific men and to attract a satisfactory quota of the best intellects of the country to the study of science. Moreover, private benefactors have not been as numerous as in some other countries in respect of those departments of scientific work which are either non-utilitarian or not immediately or obviously so. We have been lacking alike in science organisation and in effective cooperation in work.

It has been attempted to overcome defects in training for scientific pursuits by the construction of royal roads to scientific knowledge. Engineering students have been urged to forego the study of Euclid, and, as a substitute, to practise drawing triangles and squares; it has been pointed out to them that mathematical study has but one object, viz., the practical carrying out of mathematical operations; that a collection of mathematical rules of thumb is what they should aim at; that a knowledge of the meaning of processes may be left out of account so long as a sufficient grasp of the application of the resulting rules is acquired. In particular, it has been stated that the study of the fundamental principles of the infinitesimal calculus may be profitably deferred indefinitely so long as the student is able to differentiate and integrate a few of the simplest functions that are met with in pure and applied physics. The advocates of these views are, to my mind, urging a process of "cramming" for the work of life which compares unfavourably with that adopted by the so-called "crammers" for examinations; the latter I believe to be, as a rule, much maligned individuals, who succeed by good organisation, hard work and personal influence, where the majority of public and private schools fail; the examinations for which their students compete encourage them to teach their pupils to think, and not to rely principally upon remembering rules. The best objects of education, I believe, are the habits of thought and observation, the teaching of how to think, and the cultivation of the memory; and examiners of experience are able to a considerable extent to influence the teaching in these respects; they show the teachers the direction in which they should look for success. The result has been that the "crammer" for examinations, if he ever existed, has disappeared. But what can be said for the principle of cramming for the work of one's life? Here an examination would be no check, for examiners imbued with the same notion would be a necessary part of the system; the awakening of the student would come, perhaps slowly, but none the less inevitably; he might exist for a while on his formulæ and his methods, but with the march of events, resulting in new ideas, new apparatus, new designs, new inventions, new materials requiring the utmost development of the powers of the mind, he will certainly find himself hopelessly at sea and in constant danger of discovering that he is not alone in thinking himself an impostor. And an impostor he will be if he does not by his own assiduity cancel the pernicious effects of the system upon which he has been educated. I do not, I repeat, believe in royal roads, though I appreciate the advantage of easy coaches in kindred sciences. In the science to which a man expects to devote his life, the progress of which he hopes to further, and in which he looks for his life's success, there is no royal road. The neglect of science is not to be remedied by any method so repugnant to the scientific spirit; we must take the greater, knowing that it includes the less, not the less, hoping that in some happy-go-lucky way the greater will follow.

At the beginning of the nineteenth century it was possible for most workers to be well acquainted with nearly all important theories in any division of science; the number of workers was not great, and the results of their labours were for the most part concentrated in treatises and in a few publications especially devoted to science; it was comparatively easy to follow what was being done. At the present time the state of affairs is different. The number of workers is very large; the treatises and periodical scientific journals are very numerous; the ramifications of investigation are so complicated that it is scarcely possible to acquire a competent knowledge of the progress that is being made in more than a few of the subdivisions of any division of science. Hence the so-called specialist has come into being.

Evident though it be that this is necessarily an age of specialists, it is curious to note that the word "specialist" is often used as a term of opprobrium, or as a symbol of narrow-mindedness. It has been stated that most specialists run after scientific truth in intellectual blinkers; that they wilfully restrain themselves from observing the work of others who may be even in the immediate neighbourhood; that even when the line of pursuit intersects obviously other lines, such intersection is passed by without remark; that no attention is paid to the existence or the construction of connecting lines; that the necessity for collaboration is overlooked; that the general advance of the body of scientific truth is treated as of no concern; that absolute independence of aim is the thing most to be desired. I propose to inquire into the possibility of such an individual existing as a scientific man.

I take as a provisional definition of a specialist in science one who devotes a very large proportion of his energies to original research in a particular subdivision of his subject. It will be sufficient to consider the subjects that come under the purview of Section A, though it will be obvious that a similar train of reasoning would have equal validity in connection with the subjects included in any of the other sections. I take the word "specialist" to denote a man who makes original discoveries in some branch of science, and I deny that any other man has the right, in the modern meaning of the word, to be called by others, or to call himself, a specialist. I would not wish to be understood to imply a belief that a truly scientific man is necessarily a specialist; I do believe that a scientific man of high type is almost invariably an original discoverer in one or more special branches of science; but I can conceive that a man may study the mutual relations of different sciences and of different branches of the same science and may throw such an amount of light upon the underlying principles as to be in the highest degree scientific. I will now advance the proposition that, with this exception, all scientific workers are specialists; it is merely a question of degree. An extreme specialist is that man who makes discoveries in only one branch, perhaps a very narrow branch, of his subject. I shall consider that in defending him I am *a fortiori* defending the man who is a specialist, but not of this extreme character.

A subject of study may acquire the reputation of being narrow either because it has for some reason or other not attracted workers and is in reality virgin soil only awaiting the arrival of a husbandman with the necessary skill, or because it is an extremely difficult subject which has resisted previous attempts to elucidate it. In the latter case, it is not likely that a scientific man will obstinately persist in trying to force an entrance through a bare blank wall. Either from weariness in striving or from the exercise of his judgment he will turn to some other subdivision which appears to give greater promise of success. When the subject is narrow merely because it has been overlooked, the specialist has a grand opportunity for widening it and freeing it from the reproach of being narrow; when it is narrow from its inherent difficulty he has the opportunity of exerting his full strength to pierce the barriers which close the way to discoveries. In either case the specialist, before he can determine the particular subject which is to engage his thoughts, must have a fairly wide knowledge of the whole of his subject. If he does not possess this he will most likely make a bad choice of particular subjects, or, having made a wise selection, he will lack an essential part of the mental equipment necessary for a successful investigation. Again, though the subject may be a narrow one, it by no means follows that the appropriate or possible methods of research are prescribed within narrow limits. I will instance the Theory of Numbers, which, in comparatively recent times, was a subject of small extent and of restricted application to other branches of science. The problems that presented themselves naturally, or were brought into prominence by the imaginations of great intellects, were fraught with difficulty. There seemed to be an absence, partial or complete, of the law and order that investigators had been accustomed to find in the wide realm of continuous quantity. The country to be explored was found to be full of pitfalls for the unwary. Many a lesson concerning the danger of hasty generalisation had to be learnt and taken to heart. Many a false step had to be retraced. Many a road which a first reconnaissance had shown to be straight for a short distance was found, on further exploration, to change suddenly its direction and to break up into a number of paths which wandered in a fitful manner in country of increasing natural difficulty. There were few vanishing points in the perspective. Few, also, and insignificant were the peaks from which a general notion could be gathered of any considerable portion of the country. The surveying instruments were inadequate to cope with the physical characters of the land. The province of the Theory of Numbers was forbidding. Many a man returned empty-handed and baffled from the pursuit, or else was drawn into the vortex of a kind of maelström and had his heart crushed out of him. But early in the last century the dawn of a brighter day was breaking. A combination of great intellects—Legendre, Gauss, Eisenstein, Stephen Smith, &c.—succeeded in adapting some of the existing instruments of research in continuous quantity to effective use in discontinuous quantity. These adaptations are of so difficult and ingenious a nature that they are to-day, at the commencement of a new century, the wonder and, I may add, the delight of beholders. True it is that the beholders are few. To attain to the point of vantage is an arduous task demanding alike devotion and courage. I am reminded, to take a geographical analogy, of the Hamilton Falls, near Hamilton Inlet, in Labrador. I have been informed that to obtain a view of this wonderful natural feature demands so much time and intrepidity, and necessitates so many collateral arrangements, that a few years ago only nine white men had feasted their eyes on falls which are finer than those of Niagara. The labours of the mathematicians named have resulted in the formation of a large body of doctrine in the Theory of Numbers. Much that, to the superficial observer, appears to lie on the threshold of the subject is found to be deeply set in it and to be only capable of attack after problems at first sight much more complicated have been solved. The mirage that distorted the scenery and obscured the perspective has been to some extent dissipated; certain vanishing points have been ascertained; certain elevated spots giving extensive views have been either found or constructed. The point I wish to urge is that these specialists in the Theory of Numbers were successful for the reason that they were not specialists at all in any narrow meaning of the word. Success was only possible because of the wide learning of the investigator; because of his accurate knowledge of the instruments that had been made effective in other branches; because he had grasped the underlying principles which caused those instruments to be effective in particular cases. I am confident that many a worker who has been the mark of sneer and of sarcasm from the supposed extremely special character of his researches would be found to have devoted the larger portion of his time to the study of methods which had been available in other branches, perhaps remote from the one which was particularly attracting his attention. He would be found to have realised that analogy is often the finger-post that points the way to useful advance; that his mind had been trained and his work assisted by studying exhaustively the successes and failures of his fellow-workers. But it is not only existing methods that may be available in a special research.

Furthermore, a special study frequently creates new methods which may be subsequently found applicable in other branches. The Theory of Numbers furnishes several beautiful illustrations of this. Generally, the method is more important than the immediate result. Though the result is the offspring of the method, the method is the offspring of the search after the result. The Law of Quadratic Reciprocity, a cornerstone of the edifice, stands out not only for the influence it has exerted in many branches, but also for the number of new methods to which it has given birth, which are now a portion of the stock-in-trade of a mathematician. Euler, Legendre, Gauss, Eisenstein, Jacobi, Kronecker, Poincaré and Klein are great names that will be for ever associated with it. Who can forget the work of H. J. S. Smith on homogeneous forms and on the five-square theorem, work which gave rise to processes that have proved invaluable over a wide field, and which supplied many connecting links between departments which were previously in more or less complete isolation?

In this connection I will further mention two branches with which I may claim to have a special acquaintance—the theory of invariants and the combinatorial analysis. The theory of invariants was evolved by the combined efforts of Boole, Cayley, Sylvester and Salmon, and has progressed during the last sixty years with the cooperation, amongst others, of Aronhold, Clebsch, Gordan, Brioschi, Lie, Klein, Poincaré, Forsyth, Hilbert, Elliott and Young. It involves a principle which is of wide significance in all the subject-matters of inorganic science, of organic science, and of mental, moral and political philosophy. In any subject of inquiry there are certain entities, the mutual relations of which under various conditions it is desirable to ascertain. A certain combination of these entities may be found to have an unalterable value when the entities are submitted to certain processes or are made the subjects of certain operations. The theory of invariants in its widest scientific meaning determines these combinations, elucidates their properties, and expresses results when possible in terms of them. Many of the general principles of political science and economics can be expressed by means of invariantive relations connecting the factors which enter as entities into the special problems. The great principle of chemical science which asserts that when elementary or compound bodies combine with one another the total weight of the materials is unchanged, is another case in point. Again, in physics, a given mass of gas under the operation of varying pressure and temperature has the well-known invariant, pressure multiplied by volume and divided by absolute temperature. Examples might be multiplied. In mathematics the entities under examination may be arithmetical, algebraical, or geometrical; the processes to which they are subjected may be any of those which are met with in mathematical work. It is the *principle* which is so valuable. It is the *idea* of invariance that pervades to-day all branches of mathematics. It is found that in investigations the invariantive fractions are those which persist in presenting themselves, even when the processes involved are not such as to ensure the invariance of those functions. Guided by analogy may we not anticipate similar phenomena in other fields of work?

The combinatorial analysis may be described as occupying an extensive region between the algebras of discontinuous and continuous quantity. It is to a certain extent a science of enumeration, of measurement by means of integers as opposed to measurement of quantities which vary by infinitesimal increments. It is also concerned with arrangements in which difference of quality and relative position in one, two, or three dimensions are factors. Its chief problem is the formation of connecting roads between the sciences of discontinuous and continuous quantity. To enable, on the one hand, the treatment of quantities which vary *per saltum*, either in magnitude or position, by the methods of the science of continuously varying quantity and position, and on the other hand to reduce problems of continuity to the resources available for the management of discontinuity. These two roads of research should be regarded as penetrating deeply into the domains which they connect.

In the early days of the revival of mathematical learning in Europe the subject of "combinations" cannot be said to have rested upon a scientific basis. It was brought forward in the shape of a number of isolated questions of arrangement, which were solved by mere counting. Their solutions did not further the general progress, but were merely valuable in connection with the special problems. Life and form, however, were infused when it was recognised by De Moivre, Bernoulli and others that it was possible to create a science of probability on the basis of enumeration and arrangement. Jacob Bernoulli, in his "Ars Conjectandi," 1713, established the fundamental principles of the Calculus of Probabilities. A systematic advance in certain questions which depend upon the partitions of numbers was only possible when Euler showed that the identity $x^a x^b = x^{a+b}$ reduced arithmetical addition to algebraical multiplication and *vice versâ*. Starting with this notion, Euler developed a theory of generating functions on the expansion of which depended the formal solutions of many problems. The subsequent work of Cayley and Sylvester rested on the same idea, and gave rise to many improvements. The combinations under enumeration had all to do with what may be termed arrangements on a line subject to certain laws. The results were important algebraically, as throwing light on the theory of Algebraic series, but another large class of problems remained untouched, and was considered as being both outside of the scope and beyond the power of the method. I propose to give some account of these problems, and to give a short history of the way in which a method of solution has been reached. It will be gathered from remarks made above that I regard any department of scientific work which seems to be narrow or isolated as a proper subject for research. I do not believe in any branch of science or subject of scientific work being destitute of connection with other branches. If it appears to be so, it is especially marked out for investigation by the very unity of science. There is no necessarily pathless desert separating different regions. Now a department of pure mathematics which appeared to be somewhat in this forlorn condition a few years ago was that which included problems of the nature of the magic square of the ancients. Conceive a rectangular lattice or generalised chess board (*cf.* "Gitter," Klein), whose compartments are situations for given numbers or quantities, so that there is a rectangular array of certain entities. The general problem is the enumeration of the arrays when both the rows and the columns of the lattice satisfy certain conditions. With the simplest of such problems certain progress had undoubtedly been made. The article on Magic Squares in the "Encyclopædia Britannica" and others on the same subject in various scientific publications are examples of such progress, but the position of isolation was not sensibly ameliorated. Again, the well-known "problème des rencontres" is an instance in point. Here the problem is to place a number of different entities in an assigned order in a line and beneath them the same entities in a different order subject to the condition that the entities in the same vertical line are to be different. This easy question has been solved by generating functions, finite differences, and in many other ways. In fact, when the number of rows is restricted to two the difficulties inherent in the problem when more than two rows are in question do not present themselves. The problem of the Latin Square is concerned with a square of order n and n different quantities which have to be placed one in each of the n^2 compartments in such wise that each row and each column contains each of the quantities. The enumeration of such arrangements was studied by mathematicians from Euler to Cayley without any real progress being made. In reply to the remark "Cui bono?" I should say that such arrangements have presented themselves for investigation in other branches of mathematics. Symbolical algebras and in particular the theory of discontinuous groups of operations have their laws defined by what Cayley has termed a multiplication table. Such multiplication tables are necessarily Latin Squares, though it is not conversely true that every Latin Square corresponds to a multiplication table. One of the most important questions awaiting solution in connection with the theory of finite discontinuous groups is the enumeration of the types of groups of given order or of Latin Squares which satisfy additional conditions. It thus comes about that the subject of Latin Squares is important in mathematics, and some new method of dealing with them seemed imperative.

A fundamental idea was that it might be possible to find some mathematical operation of which a particular Latin Square might be the diagrammatic representative. If, then, a one-to-one correspondence could be established between such mathematical operations and the Latin Squares, the enumeration might conceivably follow. Bearing this notion in mind, consider the differentiation of x^n with regard to x. Noticing that the result is nx^{n-1} (n an integer), let us inquire whether we can break up the operation of differentiation into n elementary portions, each of which will contribute a unit to the resulting coefficient n. If we write down x^n as the product of n letters, viz. $xxxx$ . . ., it is obvious that if we substitute unity in place of a single x in all possible ways, and add together the results, we shall obtain nx^{n-1}. We have, therefore, n different elementary operations, each of which consists in substituting unity for x. We may denote these diagrammatically by

and from this point of view $\frac{d}{dx}$ is a combinatorial symbol, and denotes by the coefficient n the number of ways of selecting one out of n different things.

Similarly, the higher differentiations give rise to diagrams of two or more rows, the numbers of which are given by the coefficients which result from such differentiations. Following up this clue much progress has been made. For a particular problem success depends upon the design, on the one hand, of a function, on the other hand, of an operation such that diagrams make their appearance which have a one-to-one correspondence with the entities whose enumeration is sought. For a general investigation, however, it is more scientific to start by designing functions and operations, and to then ascertain the problems of which the solution is furnished. The difficulties connected with the Latin Square and with other more general questions have in this way been completely overcome.

The second new method in analysis that I desire to bring before the Section had its origin in the theory of partition. Diophantus was accustomed to consider algebraical questions in which the symbols of quantity were subject to certain conditions, such, for instance, that they must denote positive numbers or integer numbers. A usual condition with him was that the quantities must denote positive integers. All such problems, and particularly those last specified, are qualified by the adjective Diophantine. The partition of numbers is then on all fours with the Diophantine equation

$$\alpha+\beta+\gamma+ \dots +\nu=n,$$

a further condition being that one solution only is given by a group of numbers α, β, γ . . . satisfying the equation; that in fact permutations amongst the quantities α, β, γ . . . are not to be taken into account. This further condition is brought in analytically by adding the Diophantine inequalities

$$\alpha \geqq \beta \geqq \gamma \geqq . . . \geqq \nu \geqq 0$$

ν in number. The importation of this idea leads to valuable results in the theory of the subject which suggested it. A generating function can be formed which involves in its construction the Diophantine equation and inequalities, and leads after treatment to a representative as well as enumerative solution of the problem. It enables further the establishment of a group of fundamental parts of the partitions from which all possible partitions of numbers can be formed by addition with repetition. In the case of simple unrestricted partition it gives directly the composition by rows of units which is in fact carried out by the Ferrers-Sylvester graphical representation and has led in the hands of the latter to important results in connection with algebraical series which present themselves in elliptic functions and in other departments of mathematics. Other branches of analysis and geometry supply instances of the value of extreme specialisation.

What we require is not the disparagement of the specialist but the stamping out of narrow-mindedness and of ignorance of the nature of the scientific spirit and of the life-work of those who devote their lives to scientific research. The specialist who wishes to accomplish work of the highest excellence must be learned in the resources of science and have constantly in mind its grandeur and its unity.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY PROF. J. COSSAR EWART, M.D., F.R.S., PRESIDENT OF THE SECTION.

The Experimental Study of Variation.

THE study of variation may be said to consist (1) in noting and classifying the differences between parents and their offspring; and (2) in determining by observation and experiment the causes of these differences, especially why only some of them are transmitted to future generations. The facts of variation having been dealt with at considerable length in a recent work by Mr. Bateson, I shall discuss chiefly the causes of variation.

Though for untold ages parents have doubtless observed differences in the form and temperament of their children, and though breeders have long noted unlooked-for traits in their flocks and herds, the systematic study of variation is of very recent date. This is not surprising, for while the belief in the immutability of species prevailed, there was no special incentive either to collect the facts or inquire into the causes of variation; and since the appearance in 1859 of the "Origin of Species" biologists have been mainly occupied in discussing the theory of natural selection. Now that discussions as to the nature and origin of species no longer occupy the chief attention of biologists, variability—the fountain and origin of progressive development—is likely to receive an ever-increasing amount of notice. Strange as it may appear, naturalists at the end of the eighteenth century concerned themselves more with the causes of variation than their successors at the end of the nineteenth. Buffon, who discussed at some length nearly all the great problems that interest naturalists to-day, after considering variation arrived at the conclusion that it was due to the direct action of the environment, and even invented a theory (strangely like Darwin's theory of pangenesis) to explain how somatic were converted into germinal variations. Erasmus Darwin and Lamarck also had views as to the causes of variation. Erasmus Darwin believed variability resulted from the efforts of the individual, new structures being gradually evolved by the organisms constantly endeavouring to adapt themselves to their surroundings. Lamarck about the same time endeavoured to prove that changes in the environment produced new needs, which in turn led to the formation of new organs and the modification of old ones, use being specially potent in perfecting the new, disuse in suppressing the old. Both Erasmus Darwin and Lamarck, without attempting, or apparently even seeing the need of, any such explanation as pangenesis offered, assumed that definite acquired modifications were transmitted to the offspring, and they both further assumed that variations occurred not in many but in a single definite direction; hence they had no need to postulate selection. The speculations of Erasmus Darwin and Lamarck having had little influence, it fell to Charles Darwin to construct new and more lasting foundations for the evolution theory.

Charles Darwin, clearly realising that variation occurs in many different directions, arrived at the far-reaching conclusion that the best adapted varieties are selected by the environment, and thus have a chance of giving rise to new species. Though impressed with the paramount importance of selection, Charles Darwin realised that "its action absolutely depends on what we in our ignorance call spontaneous or accidental variation."[1] Darwin, however, concerned himself to the last more with selection than with variation, doubtless because he believed variability sinks to a quite subordinate position when compared with natural selection. As variations stand in very much the same relation to selection as bricks and other formed material stand to the builder, Darwin was perhaps justified in rating so high the importance of the principle with which his name will ever be intimately associated. Though Darwin considered variability of secondary importance, it may be noted that he did more than any other naturalist to collect the facts of variation, and he moreover considered at some length the causes of variation. He regarded with most favour the view "that variations of all kinds and degrees are directly or indirectly caused by the conditions of life to which each being or more especially its ancestors have been exposed."[2] Of all the causes which induce variability, he believed excess of food was probably the most powerful.[3] In addition to variations which arise spontaneously in obedience to fixed and immutable laws, Darwin believed with Buffon that variations were produced by the direct action of the environment, and with Lamarck by the use and disuse of parts; and he accounted for the inheritance of such variations by his theory of pangenesis. Darwin seems always to have regarded the direct action of the environment and use and disuse as, at the most, subsidiary causes of variation; but Mr. Herbert Spencer and his followers regard "use-inheritance" as an all-important factor in evolution; while Cope and his followers in America, by a mixture of "use-inheritance" (Konetogenesis) and Lamarck's neck-stretching theory (Archæsthetism), apparently see their way to account for the evolution of animals with but little help from natural selection.

Prof. Weismann and others, however, have recently given strong reasons for the belief that all variation is the result of changes in the germ-plasm ultimately due to external stimuli, the environment acting directly on unicellular, indirectly on multicellular organism. It is convenient to speak of biologists who believe with Mr. Herbert Spencer in the law of use and disuse (use-inheritance) as Neo-Lamarckians, and of those who with Weismann refuse to accept the doctrine of the transmission of definite acquired characters, and in the case of multicellular organisms the direct influence of the environment as a cause of variation, as Neo-Darwinians. In discussing variability I shall assume that all variations are transmitted by the germ-cells; that the primary cause of variation is always the effect of external influences, such as food, temperature, moisture, &c.; and that "the origin of a variation is equally independent of selection and amphimixis" (Weismann, "The Germ-Plasm," p. 431), amphimixis being simply the means by which effect is given to differences inherited, and to the differences acquired by the germ-cells during their growth and maturation.

Theoretically the offspring should be an equal blend of the parents and (because of the tendency to reversion) of their respective ancestors. In as far as the offspring depart either in an old or in a new direction from this ideal intermediate condition they may be said to have undergone variation. The more obvious variations consist of a difference in form, size and colour, in the rate of growth, in the period at which maturity is reached, in the fertility, in the power to withstand disease and changes in the surroundings, of differences in temperament and instincts, and in the aptitude to learn. In the members of a human family there may be great dissimilarity, and the dissimilarity may be even greater in the members of a single brood or litter of domestic animals, especially if the parents belong to slightly different breeds.

[1] "Animals and Plants," vol. ii, p. 206.

[2] *Ibid.*, vol. ii, p. 240. Elsewhere he says we are "driven to the conclusion that in most cases the conditions of life play a subordinate part in causing any particular modification."

[3] *Ibid.*, vol. ii, p. 282.

Frequently some of the offspring closely resemble the immediate ancestors, while others suggest one or more of the remote ancestors, are nearly intermediate between the parents, or present quite new characters. Similarly seedlings from the same capsule often differ. Can we by way of accounting for these differences only with Darwin say variations are due to fixed and immutable laws, or at the most subscribe to the assertion of Weismann, that they are "due to the constant recurrence of slight inequalities of nutrition of the germ-plasm"? ("Germ-Plasm," p. 431). Weismann accounts for ordinary variation by saying that the reduction of the germ-plasm during the maturation of the germ-cell is qualitative as well as quantitative, *i.e.* that the germ-plasm retained in the ovum to form the female pro-nucleus is different from the germ-plasm discharged in the second polar body. He accounts for discontinuous variation and "sports" by "the permanent action of uniform changes in nutrition" ("Germ-Plasm," p. 431). These uniform changes in nutrition by modifying in a constant direction susceptible groups of germ-units (determinants) after a time giving rise to new, it may be pronounced variation. Must we rest satisfied with these assumptions, or is it possible to account for some of the variability met with by, say, differences in the maturity of the parents or of the germ-cells, by the germ-cells having been influenced by interbreeding or intercrossing, or by the soma in which they are lodged having been invigorated by a change of food, or habitat, or deteriorated by unfavourable surroundings or disease? In other words, are there valid reasons for believing that the germ-cells are extremely sensitive to changes in their immediate environment, *i.e.*, to modifications of the body, or soma containing them, and that the characters of the offspring depend to a considerable extent on whether the germ-cells have recently undergone rejuvenescence?

Obviously if the offspring, other things being equal, vary with the age of the parents, the ripeness of the germ-cells and with the bodily welfare, the qualitative division of the nucleus on which Weismann so much relies as an explanation of ordinary variation will prove inadequate.

Is Age a Cause of Variation?

During the course of my experiments on Variation I endeavoured to find an answer to the question, "Is Age a Cause of Variation?" During development and while nearly all the available nourishment is required for building up the organs and tissues of the body, the germ-cells remain in a state of quiescence. Sooner or later, however, they begin to mature, and eventually in most cases escape from the germ-glands. I find the first germ-cells ripened often prove infertile. When, *e.g.*, pigeons from the same nest are isolated and allowed to breed as soon as mature, they seldom hatch out birds from the first pair of eggs, and though quite vigorous in appearance they may only hatch a single bird from the second pair of eggs. The same result generally follows mating very young but quite unrelated pigeons; but when a young hen bird is mated with a vigorous, well-matured male, or a young male is mated with a vigorous, well-matured female, the eggs generally prove fertile from the first. The germ-cells are, as far as can be determined, structurally perfect from the outset; and that they only fail in vigour is practically proved by the fact that though the conjugation of germ-cells from two young birds leads to nothing, the conjugation of germ-cells from quite young birds with germ-cells from mature birds generally at once results in offspring.

The following experiments indicate how age may prove a cause of variation. Last autumn I received from Islay two young male blue-rock pigeons which, though bred in captivity, were believed to be as pure as the wild birds of the Islay caves. In February last one of the young blue-rocks, while still immature, was placed with an inbred white fantail, the other with an extremely vigorous well-matured black barb. In course of time a pure-white bird was reared by the white fantail, and two dark birds by the black barb. Owing probably to the fantail being inbred and the blue-rock being still barely mature, the young white bird died soon after leaving the nest. No birds were hatched from the second and third pairs of eggs laid by the fantail, but from the fourth pair two birds were hatched which are now nearly full-grown. These young birds are of a darker shade of blue, and look larger and more vigorous than their blue-rock sire. As in the Indian variety of the blue-rock pigeon the croup is blue, and, as in some of the Eastern blue-rocks, the wings are slightly chequered. They, however, only essentially differ from their sire in having four extra feathers in the tail. The first pair of birds hatched by the black barb when they reached maturity early in August might have passed for young barbs with somewhat long beaks. Since the first pair were hatched in March the blue-rock and black barb have reared six other birds. One of the second brood closely resembles the first birds hatched; the other is of a greyish colour, with slightly mottled wings, a long beak, and a tail bar. The birds of the third nest are both of a greyish colour, but have indistinct wing bars as well as a tail bar. Of the fourth pair of young, one is greyish like the birds of the third nest, the other is of a dark blue colour with slightly chequered wings, and a head, beak and bars as in its blue-rock sire. The gradual change from black to dark blue in the blue-rock barb crosses is very remarkable. I can only account for the almost mathematical regularity of the change by supposing it has kept pace with a gradual increase in the vigour or prepotency in the young blue-rock. Eventually the offspring of the blue-rock mated to the black barb, like the offspring of its brother with the white fantail, may be of a slaty blue colour, and otherwise resemble a wild blue-rock pigeon. Many breeders would explain the offspring taking more and more after the sire by the doctrine of Saturation—a doctrine that finds much favour amongst breeders—but as identical results were obtained when young females were mated with well-matured males the saturation explanation falls to the ground.

Like results were obtained by breeding young grey quarter-wild rabbits with an old white Angora buck: the first young were white, the subsequent young were white, grey and bluish grey. From these results it follows that when old and young but slightly different members of a variety or species are marked a wonderfully perfect series of intermediate forms is likely to be produced. Amongst wild animals the young males rarely have a chance of breeding with the young females; hence amongst wild animals, owing to age being a cause of variation, a considerable amount of material is doubtless constantly provided for selection, thus affording a variety an additional chance of adapting itself to slight fluctuations in the environment.

In the results obtained by crossing mature, vigorous, and, in some cases, inbred males with barely mature females, an explanation may be found why in some families the same features have persisted almost unaltered for many generations; why in his features the squire of to-day sometimes exactly reproduces the lines of his ancestors, as seen in portraits and monumental brasses. It should, however, be borne in mind that highly prepotent forms are capable from the first of so completely controlling the development that they transmit their peculiar traits to all their offspring.

Is Ripeness of the Germ-Cells a Cause of Variation?

While difference in age may sometimes account for the earlier broods and litters resembling one of the parents, it fails to account for the very pronounced variation often found in a single brood or litter, and for much of the dissimilarity between members of the same human family. When a *single* fertilised germ-cell, as occasionally happens, gives rise to twins, they are always identical; hence it may be assumed the differences in members of the same family have their source in differences in the germ-cells from which they spring. If the offspring vary with the maturity of the soma, it may also vary with the maturity of the germ-cells, or at least with their condition at the moment of conjugation.

Some years ago Mr. H. M. Vernon, when hybridising echinoderms, discovered that "the characteristics of the hybrid offspring depend directly on the relative degrees of maturity of the sexual products" (*Proceedings* Royal Society, vol. lxiii. May 1898). Mr. Vernon found subsequently that over-ripe (stale) ova fertilised with fresh sperms gave very different results from fresh ova fertilised with over-ripe (stale) sperms, from which he inferred that over-ripeness (staleness) is a very potent cause of variation (*ibid.*, vol. lxv. November 1899).

I find that if a well-matured rabbit doe is prematurely (*i.e.*, some time before ovulation is due) fertilised by a buck of a different strain, the young take after the sire; when the fertilisation takes place at the usual time, some of the young resemble the buck, some the doe, while some present new characters or reproduce more or less accurately one or more of the ancestors. When, however, the mating is delayed for about thirty hours beyond the normal time, all the young, as a rule, resemble the doe. It may hence be inferred that in mammals, as in echinoderms, the characters of the offspring are related to the condition of the germ-cells at the moment of conjugation, the offspring resulting from the union of equally ripe germ-cells differing from the offspring developed from the conjugation of ripe and unripe germ-cells, and still more from the union of fresh and over-ripe germ-cells. This conclusion may be said to be in harmony with the view expressed by Darwin, that the causes which induce variability probably act "on the sex elements before impregnation has been effected" ("Animals and Plants," vol. ii. p. 259). The results already obtained, though far from answering the question why there is often great dissimilarity between members of the same family, may lead to further experiment, and especially to more complete records being kept by breeders. It is unnecessary to point out what a gain it would be were breeders able to regulate, even to a small extent, the characters of the offspring.

Is the Condition of the Soma a Cause of Variation?

There is a considerable amount of evidence in support of the view that changes in any part of the body or soma which affect the general welfare influence the germ-cells. This is but what might be expected if the soma in the metazoa is to the germ-cells what the immediate surroundings are to the protozoa. The soma from the first forms a convenient nidus for the germ-cells, and when sufficiently old and sufficiently nourished it provides the stimuli by which the ripening (maturing) of the germ-cells is effected. If in the case of the protozoa variation is due to the direct action of the environment, it may be inferred that in the metazoa variations of the germ-cells result from the direct action of the soma, *i.e.*, from the direct action on the germ-cells of their immediate environment. This, however, is quite a different thing from saying that definite somatic variations are incorporated in the germ-cells (converted into germinal variations) and transmitted to the offspring.

It may first be asked, Does disease in as far as it reduces the general vigour or interferes with the nutrition of the germ-cells act as a cause of variation? I recently received a number of blue-rock pigeons from India infected with a blood parasite (Halteridium) not unlike the organism now so generally associated with malaria. In some pigeons the parasites were very few in number, in others they were extremely numerous. The eggs of a pair of these Indian birds with numerous parasites in the blood proved infertile. Eggs from a hen with numerous parasites fertilised by a cock with a few parasites proved fertile, but the young died before ready to leave the nest. An old male Indian bird, however, with comparatively few parasites mated with a mature half-bred English turbit produced a single bird. The half-bred turbit has reddish wings and shoulders, but is otherwise white. The young bird by the Indian blue-rock is of a reddish colour nearly all over, but in make not unlike the cross-bred turbit hen.

Some time before the second pair of eggs were laid the parasites had completely disappeared from the Indian bird, and he looked as if he had quite recovered from his long journey, as well as from the fever. In due time a pair of young were hatched from the second eggs, and as they approached maturity it became more and more evident that they would eventually present all the distinctive points of the wild-rock pigeon.[1] The striking difference between the first bird reared and the birds of the second nest might, however, be due not to the malaria parasites but to the change of habitat.

Against this view, however, is the fact that another Indian bird infected to about the same extent as the mate of the half-bred red turbit counted for little when mated with a second half-bred turbit; while two Indian birds in which extremely few parasites were found at once produced blue-rock-like birds when bred—one with a fantail, the other with a tumbler.

Another possible explanation of the difference between the bird of the first and the birds of the second nest is that the germ-cells were for a time infected by the minute protozoan Halteridium in very much the same way as the germ-cells of ticks are infected by the parasite of Texas fever. But of this there is no evidence, for even in the half-grown birds hatched by the pure-bred malarious Indian rocks the most careful examination failed to detect any parasites in the blood. In all probability Halteridium can only be conveyed from one pigeon to another by Culex or some other gnat.

These results with pigeons suffering from malaria seem to ndicate that the germ-cells are liable to be influenced by fevers and other forms of disease that for the time being diminish the vitality of the parents. Further experiments may show that the germ-cells are influenced in different ways by different diseases.

Sometimes the germ-cells suffer from the direct action of their immediate environment, from disturbance in or around the germ-glands. If, for example, inflammation by the ducts or other channels reaches the germ-glands, the vitality of the germ-cells may be considerably diminished; if serious or prolonged, the germ-cells may be as effectively sterilised as are the bacteria of milk by boiling.

In 1900 two mares produced foals to a bay Arab which had previously suffered from a somewhat serious illness involving the germ-glands. These foals in no way suggest their sire. This year I have three foals by the same Arab after he had quite recovered: one promises to be the image of his sire, and the other two are decidedly Arab-like both in make and action.

While the germ-cells are liable to suffer when the soma is the subject of disease, there is no evidence that they are capable of being so influenced that they transmit definite or particular modifications (unless directly infected with bacteria or other minute organisms); that, *e.g.*, the germ-cells of gouty subjects necessarily give rise to gouty offspring. Doubtless if the germ-cells, because of their unfavourable immediate surroundings, suffer in vigour or vitality, the offspring derived from them are likely to be less vigorous, and hence more likely than their immediate ancestors to suffer from gout and other diseases.

It would be an easy matter to give instances of the offspring varying with the condition or fitness of the parents; but it will suffice if, before discussing intercrossing, I refer to the influence of a change of habitat.

Is Change of Habitat a Cause of Variation?

It has long been recognised that a change of surroundings may profoundly influence the reproductive system, in some cases increasing the fertility, in others leading to complete sterility. Exotic plants, sterile it may be at first, often become extremely fertile, and when thoroughly established give rise to new varieties. In the case of mares obtained from Iceland and the south of England sometimes a year elapses before they breed. An Arab-Kattiawar pony which arrived during April from India proved during the first three months quite sterile, owing, I believe, to loss of vigour on the part of the germ-cells, their vitality being only about one-tenth that of a home-bred hackney pony. But the fertility is apparently greatly impaired by even comparatively slight changes of environment. Lions which breed freely in Dublin seem to be sterile in London, and I heard recently that when bulls are changed from one district to another in the north of Ireland complete sterility is sometimes the result. The tendency of some exotic plants to "sport" after they become acclimatised is doubtless due to the fact that their new habitat is unusually favourable, their general vigour—so essential for new developments—is increased, and, probably because certain groups of germ units are constantly stimulated by the new food available, they give rise abruptly or gradually to new and it may be unexpected characters. No one doubts that the bodily vigour is liable to be impaired by fevers and other diseases, by changes in the habitat, unsuitable food, rapid and unseasonable changes of temperature, and the like; hence it will not be surprising if further investigations prove that changes in the soma, beneficial as well as injurious, are reflected in the germ-cells, and thus indirectly induce variation. Moreover there are excellent reasons for believing that the germ-cells are influenced by seasonable changes, such as moulting in birds and changing the coat in mammals. In the case of pigeons, *e.g.*, the young bred in early summer are, other things being equal, larger and more vigorous, and mature more rapidly, than birds hatched in the late summer or autumn. But however sensitive the germ-cells may be to the changes of their immediate environment, *i.e.*, the soma or body in which they are lodged, there is no evidence whatever that (as Buffon asserted and Darwin thought possible) definite changes of the soma, due to the direct action of the environment, can be imprinted on the germ-cells. By the direct action of the environment—food, temperature, moisture, &c.—the body in whole or in part may be dwarfed, increased, or otherwise modified; but such changes only influence the germ-cells in as far as they lead to modifications of the body as a whole. They may expedite or delay maturity, after the length of the reproductive period, interfere with the nutrition of the germ-cells, or retard the development of the embryo, but they seem incapable of giving rise to definite structural or functional variations in the offspring.

[1] In these young birds the breast and some of the wing feathers are imperfect. Fanciers regard this condition of the feathers as evidence of contitutional weakness.

Intercrossing and Interbreeding as Causes of Variation.

The belief was once common amongst naturalists that variability was wholly due to crossing, and at the present day naturalists and breeders alike agree that intercrossing is a potent cause of variability, and are unanimous in regarding interbreeding as an equally potent means of checking variability. The opinion is also general that intercrossing has a swamping influence; that having brought forth new forms it forthwith proceeds to destroy them. Darwin, when discussing reversion, points out that intercrossing often speedily leads to almost complete reversion to a long-lost ancestor, *i.e.*, to the loss of recently acquired and the reappearance of long lost characters "Animals and Plants," vol. i. p. 22). When, however, he comes to deal with variability, he states that "crossing, like any other change in the conditions of life, seems to be an element, probably a potent one, in causing variability (*ibid.*, vol. ii. p. 254), the offspring of the first generation being generally uniform, but those subsequently produced displaying an almost infinite diversity of character. As to the influence of inbreeding he says, "close interbreeding, if not carried to an injurious extreme, far from causing variability, tends to fix the character of each breed (*ibid.*, vol. ii. p. 251).

These statements may be quoted in support of the very common belief that intercrossing is both a potent cause of variation and of reversion; that it produces new varieties one moment and swamps them the next. Whether intercrossing may be regarded as the immediate cause of variation or of reversion (it can hardly be both) depends on what is implied by variation. Obviously variation may be either progressive or retrogressive, *i.e.*, the offspring may differ from their parents in having quite new characters or in presenting ancestral characters, or in being characterised by traits neither new nor old, due to new combinations of characters already recognised as belonging to the variety or species. When intercrossing results in the restoration of old characters, we have reversion or retrogressive variation; when to new combinations of already existing characters like new combinations in a kaleidoscope, we have new variations of a non-progressive kind, almost always characterised by more or less reversion; when, however, intercrossing results in the characters of one variety being engrafted on another, or to the appearance of characters quite new to the species, we have progressive variation. Judging from the results I have obtained, intercrossing of two distinct varieties results, as a rule, in the loss of the more striking characters of both parents, *i.e.* in more or less marked reversion, the extent of the loss generally depending on the difference between the forms crossed. For example, if an owl pigeon is crossed with a pigeon known among fanciers as an archangel, nondescript birds are obtained, which may at once, with a white fantail, give birds almost identical with a blue-rock—the common ancestor of all our breeds of pigeons. Intercrossing, on the other hand, rarely leads to the blending in one individual of the unaltered characters of two or more varieties, and it never results in the appearance of characters absolutely new to the species. In a word, the immediate result of intercrossing distinct varieties is, as a rule, more or less marked reversion. But though intercrossing usually results in retrogressive variation, it is *indirectly* an extremely potent cause of progressive variation. This is due to the fact (better realised by botanists than zoologists) that cross-bred offspring (first crosses) are (unless the parents have been enfeebled by interbreeding) endowed with an unusual amount of vigour, *i.e.*, intercrossing is of supreme importance, not only because it leads to the co-mingling of germ-plasms having different tendencies, but also and perhaps chiefly because of its rejuvenating influence. The importance of this rejuvenation is usually at once evident if intercrossing is immediately followed by interbreeding. The interbreeding of closely related forms generally reduces the vigour, and, as Darwin points out, "far from causing variability, tends to fix the character of each breed" ("Animals and Plants," vol. ii. p. 251); but the intercrossing of first crosses (or of highly vigorous individuals closely related in either the direct or the collateral line) without appreciably weakening the constitution, often results in offspring displaying, to use Darwin's words, "an almost infinite diversity of character" (*ibid.*, vol. ii. p. 256). The epidemics of variation, so often the outcome of interbreeding first or at least vigorous recently produced crosses, are apparently partly due to the union of individuals having a similar tendency checking reversion, and partly to the vigour acquired by recent intercrossing. This much may be inferred from the fact, that when interbreeding is persisted in the variability dwindles as the vigour ebbs.

Breeders agree with Darwin that first crosses are generally uniform, and that the subsequent offspring usually vary immensely; yet neither breeders nor naturalists seem to have clearly realised that interbreeding at the right moment is the *direct* cause of variation, while intercrossing is, except in very rare cases, at the most an *indirect* cause of variation.

It may be here said that it is impossible to over-estimate the importance of vigour in studying variation. Without vigour no race or breed can maintain its position; without renewed vigour it is hardly likely to develop new characters. The new vigour, as already explained, may be obtained by intercrossing; but it may also be acquired, especially in plants, by a change of surroundings accompanied by a plentiful supply of suitable food.

With rigid selection the gradual loss of vigour may escape notice, but when selection is suspended rapid deterioration (from the fancier's standpoint) is the inevitable result. If, *e.g.*, a number of pigeons, good specimens of a distinct breed, are isolated and left unmolested for a few years, they rapidly degenerate, *i.e.*, they lose their show points (be they peaks, frills, ruffs, or metallic tints) and reassume the more fixed ancestral characters. If, however, the less characteristic birds are eliminated, and high-class birds are from time to time introduced from another loft, the vigour and the distinctive traits are indefinitely preserved.

If the age and condition of the soma and the state of ripeness of the germ-cells are potent factors, and especially if vigour counts for much, the difficulties of breeders become intelligible, and the unlikeliness of intercrossing being a direct cause of variation all the more evident. The most that can be expected from intercrossing is the engrafting on one breed the characters of another. Even this rarely happens, and is only possible when the two breeds are somewhat allied. It is impossible, *e.g.*, to unite in one individual all the points of a fantail and a pouter, or of a fantail and a jacobin; but given healthy, vigorous birds, the points of an owl may be engrafted on a barb. Or to take another example, the black ears, feet, &c., of a Himalaya rabbit may be combined with the characteristic form, long hair and habits of an Angora. It may be impossible to predict what will happen when intercrossing is resorted to, but if pure-bred members of a distinct variety are experimented with —and it is useless working with either plants or animals of unknown origin—characters not already present in one of the varieties need not be looked for.

But while interbreeding at the right moment may be a cause of progressive variation, at other times it leads to what is perhaps best described as degeneration. When, *e.g.*, very young members of the same brood or litter, or unhealthy, closely related individuals, or quite mature and apparently vigorous but for several generations closely related animals are interbred, the offspring frequently differ from their parents. They are often delicate and highly sensitive, and unable to survive unless provided with highly nutritious food; and though they mature numerous germ-cells they rear but few offspring, and, what is still more striking, they are sometimes either white or all but devoid of pigment. Offspring thus characterised, especially when white or nearly white in colour, *e.g.*, nearly white pheasants, partridges, and woodcock, white specimens of the brown hare, white squirrels, &c., are sometimes regarded as distinct varieties, but when the departure from the normal colour, &c., is the result of close inbreeding it is best regarded as degeneration.

In the spring of 1900 I crossed a quarter-wild grey doe rabbit with a closely inbred black-and-white buck. The young obtained varied considerably in colour: to one of her offspring coloured like the sire, the grey doe produced a second litter, all but one decidedly lighter in colour than the sire. Two of the darker members of this litter produced almost white young, and to one of them the original grey doe has recently produced a light-coloured litter consisting of two pure white specimens, two with only a narrow dorsal band, two fawn-coloured and one black. Close interbreeding with goats and pigeons yields similar results. Birds on small remote Pacific islands are sometimes marked with irregularly disposed white patches. These pie-bald birds, like light-coloured pheasants, cream-coloured partridges and dun-coloured rooks, may also be the victims of close inbreeding.

The Swamping Effects of Intercrossing.

The question "Are new varieties liable to be swamped by intercrossing?" is perhaps the most important now pressing for an answer from biologists. What would happen, for example, if specimens of all the different breeds of cattle were set free and left unmolested on a large area? Would they some centuries hence be represented by several breeds or by one? Many would answer this question by saying that unless some of them in course of time were isolated by mountains, deserts, or other physical barriers, they would eventually through intercrossing give rise to a single breed. To this question Darwin would, I think, have given a somewhat different answer, for, while admitting "that isolation is of considerable importance in the production of new species," he was, on the whole, "inclined to believe that largeness of area is of more importance ("Origin of Species," p. 104). Unfortunately Darwin nowhere indicates how he supposed new varieties escape being swamped by intercrossing. His silence on this important point is difficult to explain, for during his lifetime the influence of intercrossing in checking progress except in one direction was often enough insisted on. Huxley tells us that in his earliest criticisms of the "Origin" "he ventured to point out that its logical foundation was insecure so long as experiments in selective breeding had not produced varieties which were more or less infertile" ("Life of Professor Huxley," p. 170). Later Moritz Wagner and others pointed out the important part physical isolation had played in the origin of species; and later still Romanes endeavoured to show how the blighting influence of free intercrossing might be overcome by physiological selection, Romanes, like Huxley, believing several varieties might be evolved in the same area if more or less mutually infertile. Evidence of the importance of physical isolation is plentiful enough; but neither has experimental nor selective breeding proved that physiological isolation has been instrumental in arresting the swamping effects of intercrossing. Hence, according to Huxley and others, the foundation of Darwin's doctrine of natural selection must still be regarded as insecure. Is intersterility the only possible means by which new varieties can be saved from premature extinction, from being destroyed before they have a chance of proving their fitness to survive? In other words, are barriers as essential among wild as among domestic animals? It does not seem to have occurred to the biologists who so fully realised the need of isolation that the old varieties instead of swamping might be swamped by the new, and that several varieties might sometimes be sufficiently exclusive to flourish and eventually give rise to a like number of species in the same area. If on an island two new varieties of sheep appeared sufficiently vigorous, or, as we say, sufficiently prepotent, to swamp all the other varieties—as the ill-favoured lean kine did eat up the fat ones—and yet so exclusive that their cross-bred offspring invariably belonged to the one new variety or the other, for their preservation fences and other barriers would be superfluous.

Is there any evidence that by prepotency the swamping of new varieties is sometimes checked, and that by exclusive inheritance two or more varieties, though mutually fertile, may persist in the same area, occasionally intercrossing with each other, but neither giving up nor taking from each other any of their distinctive characters? I have in my possession a skewbald Iceland pony that produces richly striped hybrids to a zebra, but skewbald offspring the image of herself in make, colour, and temperament to whole-coloured bay Arab and Shetland ponies. This pony instead of being swamped invariably swamps older breeds. A number of prepotent skewbald ponies, wherever placed, would (especially with the help of preferential mating) in all probability soon give rise to a distinct race such as once existed in the East. What is true of the Equidæ is equally true of other groups. Black hornless Galloway bulls are often so prepotent that their offspring with long-horned brightly-coloured Highland heifers readily pass for pure-bred Galloways. The wolf is so prepotent over the dog, as the wild rabbit, rat, and mouse are prepotent over their tame relatives. As an instance of prepotency in rabbits, I may give the results of an interbreeding experiment with a grey doe, the granddaughter of a wild rabbit, and an inbred buck richly spotted like a Dalmatian hound. Of six young in the first litter three were like the sire. To one of her sons, the grey doe next produced eight young, all richly spotted, and subsequently to one of her spotted grandsons she produced two spotted, two white, and two grey offspring. Similar results are obtained with plants; hybrid orchids, *e.g.*, sometimes reproduce all the characters of one of the parents.

It need hardly be insisted on that if new varieties, well adapted for their environment, are not only sufficiently prepotent to escape being swamped by other varieties, but are also, like the spotted rabbit, able to hand on the prepotency almost unimpaired to a majority of their descendants, progressive development along a definite line will be possible. But of even more importance than prepotency is what for want of a better name may be known as exclusive inheritance. Recently a vigorous mature Indian blue-rock pigeon mated with an inbred and equally mature fantail, hatched and reared two birds, one exactly like a blue-rock, but with fourteen instead of twelve tail feathers; the other characterised by all the points of a high-class fantail, the tail feathers being thirty in number—two fewer than in the fantail parent, but eighteen more than in the blue-rock parent. In this case the blue-rock was the exclusive bird, the fantail having previously produced birds with only sixteen feathers in the tail when mated with an ordinary dovecot pigeon. A still more striking example of exclusive inheritance we have in the crow family. The carrion crow and the hooded crow are so unlike in colour that they were long regarded as two distinct species; now they are said to be two varieties of the same species. The carrion crow is black all over, but in the hooded crow the breast and back are grey. These two crows cross freely (but for this they would probably still rank as distinct species); but in the crossbred young there is never any blending—they are either black or grey, usually both varieties occurring in the same nest. Similar exclusiveness occurs amongst mammals. When distinct varieties of cats are crossed, some of the young usually resemble one breed, some the other, and the distinctions may persist for several generations. A white crossed with a tabby-coloured Persian cat produced a pair of white and a pair of tabby-coloured young; the two white cats when interbred also produced two white and two tabby-coloured individuals. I find cats are far more exclusive than rabbits; perhaps it is partly for this reason we have so many species and varieties of wild cats, so few species and varieties of wild rabbits. Another very striking instance of exclusiveness we have in the Ancon or "Otter" sheep common in New England at the end of the eighteenth century. This breed, which was characterised by short crooked legs and a long back like a turnspit dog, descended from a ram-lamb born in Massachusetts in 1791. The offspring of this "sport" were never intermediate in their characters; they were either like the original Ancon ram or like the breeds, some thirteen in number, with which he was mated. Frequently in the case of twins one was otter-like, the other an ordinary lamb. More remarkable still, the Ancon-like crosses, generation after generation, were as exclusive as their crooked-legged ancestor.

Another familiar example of exclusiveness we have in the peppered moth, a dark variety of which in a few years swamped the older light variety throughout a considerable part of England, and is now extending its range on the Continent. It thus appears that when a new variety is sufficiently prepotent, instead of being swamped it may actually swamp the old-established variety; and that when two or more varieties are sufficiently exclusive they may flourish side by side, and eventually give rise to two or more distinct species.

Prepotency may hence be said to supplement and complete the work of the environment. The environment seems to be mainly concerned in eliminating the unfit; whether any of the survivors persist depends not so much on their surroundings as on whether they are sufficiently prepotent and exclusive to escape being swamped by intercrossing. This way of accounting for progress in one or more directions may prove as inadequate as the one suggested by isolationists, but it has the merit of being more easily tested by experiment. It not only gets rid of the swamping bugbear, but makes it matter of indifference whether (to quote from the President's address at the last Oxford meeting of the Association) "the advantageously varied bridegroom at the one end of the wood meets the bride, who, by a happy contingency, had been advantageously varied in the same direction, and at the same time, at the other end of the wood." Further, as a highly prepotent vigorous variety can well afford to maintain a number of budding organs, it helps us to understand how luminous, electric, and certain other structures were nursed up to the point when they began to count in the struggle for existence.

Doubtful Causes of Variation.

Having indicated how maturity of the soma and of the germ-cells, and how bodily welfare and interbreeding may act as causes of variation, and also how swamping of the new variations may be checked, I shall now refer to certain supposed causes of variation.

Maternal Impressions.

I may begin with the widespread belief that the offspring are capable of being influenced in form, colour, and temperament by maternal impressions—the belief we associate with the skilful shepherd who peeled wands and stuck them up before the fulsome ewes. Muller ("Elements of Physiology," vol. ii. p. 1405) more than half a century ago, conclusively argued against the belief in maternal impressions, but the belief still prevails. I know of two able naturalists who subscribe to the maternal impression doctrine, and it is firmly held by many breeders and by not a few physicians. A writer in a recent number of a quarterly (*Bibby's Quarterly*, Autumn Number, 1900, p. 163), which circulates widely amongst farmers and stock-keepers, boldly asserts that the existence of impressions which affect progeny (more especially in colour) is a settled fact. This writer supports his case by referring to a highly successful breeder of polled Angus cattle, who considered it necessary to surround his herd "with a tight black fence in order to keep the females from dropping red calves because they saw the red herds of his neighbours." Reference is also made by this writer to the belief, common in certain parts of England, that whitewashed byres, regardless of the colour of the parents, produce light-coloured calves; that the colour of foals is often more influenced by the stable companion of the dam than by her own colour or that of the sire; and that even the colour of birds varies with the immediate surroundings, fowls, *e.g.*, however carefully penned, hatching birds resembling in colour the hens they habitually see in a neighbouring run. If maternal impressions thus influence the offspring they must be one of the most effective causes of variation. During the last six years I have bred many hundreds of animals, but the nearest approach to an instance of maternal impressions was a dark pup with a white ring half round the neck, which suggested the white metal collar sometimes worn by his sire. But similar rings round the legs and tail rather discredited the view that the white neck-ring was in any way related to the sire's nickel-plated collar. Telegony was sometimes said to be due to maternal impressions. It was doubtless for this reason that I was urged some years ago to carefully prevent the mares used in my experiments from seeing too much of the zebras. But though numerous foals have been bred from mares stabled with zebras or grazing with richly striped zebra hybrids, not a particle of evidence have I found in support of the maternal impression doctrine. The foals have neither stripes nor upright manes, and do not even attempt to mock the weird barking call of the zebra. Sheep and cattle, goats, rabbits and guinea-pigs, fowls and pigeons, have simply confirmed the results obtained with horses. This being the case, grooms may very well omit following the practice (considered so essential in Spain during the Middle Ages, and still often religiously observed in England and America) of setting "before the mares . . . the most goodly beasts" by way of hinting to them the kind of foals they are expected to produce.

The Needs of the Organism as a Cause of Variation.

No recent biologists are perhaps prepared to believe like Lamarck that the wings of birds were developed by their remote ancestors making efforts to fly; that by stretching its toes the otter acquired webbed feet; nor are they prepared to find in our new mammal, the Ocapi, evidence in support of Lamarck's contention that to meet new needs the giraffe by much stretching gradually lengthened his neck. Yet it is difficult sometimes to see any real difference between the beliefs of the new Lamarckians and the old. It is maintained, for example, "that when a certain functional activity produces a certain change in one generation it will produce it more easily the next," that, *e.g.*, flounders and their allies by constant efforts generation after generation have dragged the left eye to the right side, while by similar efforts in the turbot and certain other flat fishes the right eye has been shifted to the left side. It is not alleged by Neo-Lamarckians that globe fishes resulted from round fishes blowing themselves out, or that flounders resulted from round fishes generation after generation making efforts to flatten themselves. If by germinal variation and selection flounders were evolved out of round fishes, is it not straining at a gnat and swallowing a camel to refuse to admit that by the same factors the left eye of the flounder has been transferred from the left to the right side of the head? In the flat fishes it is not difficult to imagine how by variation and selection the eyes originally acquired the power of responding to certain external stimuli.

The Direct Action of the Environment and Use-Inheritance as Causes of Variation.

Of the doctrine of the transmission of acquired characters, still so often the subject of discussion, I need say little more than that I have failed to discover any evidence in its favour. Writing in 1876, Darwin says, "In my opinion the greatest error which I have committed has been not allowing sufficient weight to the direct action of the environment, *i.e.*, food, climate, &c., independently of natural selection" ("Life and Letters": Letter to Moritz Wagner). Darwin not only in his later years reverted to the teaching of Buffon, but in as far as he continued to believe in the "inherited effects of use and disuse" he adopted the views of Erasmus Darwin and Lamarck. While admitting that the direct action of the environment on the soma and use-inheritance are indirect—it may be potent—causes of variation, I do not believe there is any trustworthy evidence in support of the view that definite somatic variations are ever transmitted.

Telegony as a Cause of Variation.

The belief in telegony is less deserving of consideration than the doctrine of the transmission of acquired characters. Nevertheless I perhaps ought to refer to it at greater length, not so much because of its scientific importance, but because it interests all sorts and conditions of men in many different parts of the world. Telegony ("infection of the germ" of older writers) means that not only the immediate parents but also the previous mates (if any) contribute to the characters of the offspring; that, *e.g.*, a mare which had produced foals to, say, "Ladas" and "Persimmon" might thereafter give birth to a foal by "Flying Fox," to which "Ladas" and "Persimmon," as well as the actual sire, contributed some of their characteristics. Many even think a sire may transmit definite structural characters from one mate to another. If there is such a thing as telegony, if it is possible to blend without the risks of intercrossing the characteristics of several individuals or varieties, progressive development would be greatly accelerated. Though the doctrine of "infection" has probably long formed part of the breeder's creed, it received but little attention from men of science until in 1820 Lord Morton communicated a case of infection to the Royal Society, which in due time was published in the *Philosophical Transactions*. In this the most credible and best authenticated of all the cases of telegony on record a chestnut mare, after rearing a quagga hybrid, produced to a black Arabian horse three foals of a peculiar bay colour, one of them (a filly) showing more stripes than the quagga hybrid, and, according to the stud groom in charge of "the colts," characterised by a mane "which from the first was short, stiff, and upright" (*Phil. Trans.*, 1820, p. 21). Darwin, after fully considering Lord Morton's case, came to the conclusion that the chestnut mare had been infected, and this case along with others led him to believe that the first male influenced "the progeny subsequently borne by the mother to other males" ("Animals and Plants," vol. ii, pp. 435, 436.) If the upright zebra-like mane in one of the pure-bred colts and the markings on all three were the result of the chestnut mare having been first mated with a quagga, there is undoubtedly such a thing as telegony, and the presumption is that other mares first mated with a quagga or zebra and then with a black Arabian would give birth to striped offspring with a stiff if not quite upright mane. The evidence that from the first the mane of the filly was short, stiff, and upright is most unsatisfactory. It consists of an allegation by a stud groom. That the mane was upright, as in the quagga and zebra, is *a priori* improbable (1) because the mane of the quagga hybrid instead of being short and stiff was long and lank enough to arch to one side of the neck; (2) because the mane of zebra hybrids throughout the greater part of the year is so long that it falls to one or it may be both sides of the neck; and (3) because in the Equidæ an upright mane is always accompanied by a tail deficient of hairs at the root—in the filly the tail is as perfect as that of her Arab sire. We have still stronger evidence that the allegation of the groom was unfounded from drawings (of the chestnut mare, her three "colts," the black Arab, the quagga, and the quagga hybrid) by Agasse, a very trustworthy animal painter of the early part of last century. In the drawing of the filly the mane is represented as lying to one side, as in Arabs and other well-bred horses. The pictures (now in the Museum of the Royal College of Surgeons, London) were made because the subsequent foals were believed to prove the truth of the "infection" doctrine. Had the mane of the filly been erect it would hardly have escaped the keen eyes of the artist. But had Agasse by any chance missed this all-important detail, Lord Morton or some of those interested would doubtless have called his attention to the matter. If the mane of an Arab is completely removed early in the spring it is stiff, and upright in the autumn, but hanging to one side close to the neck in the following summer. When the whole circumstances are taken into consideration, there seems to me no escape from the conclusion that the mane of the filly was upright when seen by Lord Morton in August, 1820, and lying to one side when painted by Agasse the following summer, because it had been regularly cropped or at least hogged some months before Lord Morton's visit. But whatever be the explanation of the want of agreement between the mane as seen by Lord Morton and as depicted by Agasse, it will, I think, be admitted that the evidence afforded by the mane of the filly is hardly sufficient to establish the truth of the doctrine of telegony. Of still less value is the evidence afforded by the make, coat, colour and markings which were apparently too indistinct to deserve the name of stripes. The colts were decidedly Arab-like, of a bay colour marked more or less "in a darker tint." Judging from Agasse's drawings they closely resemble Arab-Indian crosses; they are, in fact, in make very like the Arab-Kattiawar horse already referred to. I have seen a bay Highland cob with as many stripes as Lord Morton's colts, and pure-bred Arabs of a dun colour with stripes on the neck and far more distinct leg bars than those depicted by Agasse. I believe the colts owed their stripes and colour not to "infection" of their dam by her previous mate the quagga, but to reversion. It is quite possible the black Arabian horse was of mixed origin; that the chestnut mare was crossbred is admitted. As in the west of Ireland the offspring of black and chestnut ponies are sometimes of a decidedly dun colour, it is not surprising that the black Arab and the half-bred chestnut had bay offspring. Neither are the stripes surprising. I recently ascertained that the chestnut mare was presented to Lord Morton (while serving with his regiment in India) by one of his officers—Mr. Boswell, of Deeside, Aberdeenshire—and that she was most likely a cross between an Arab and a country-bred pony. In Kattiawar the ponies when pure-bred are of a rufous grey colour and more or less richly striped. If in the chestnut mare there was any Kattiawar or even any native pony blood its offspring to a black sire might have been expected to be of a dun colour and striped. In a word, there is no reason for assuming that the foals would have been less striped if the chestnut mare had been mated with the black Arab first and the quagga afterwards.

By way of testing the truth of the "infection" doctrine I started, in 1895, a number of experiments, and especially arranged to repeat as accurately as possible, what is commonly called Lord Morton's experiment. Since then twelve mares after producing sixteen zebra hybrids, a mule, and a hinny have had an opportunity of supporting the telegony hypothesis by giving birth to twenty-two pure-bred foals.

During the same period Baron de Parana of Brazil has bred at least six zebra hybrids, and some of the dams of these hybrids subsequently produced ordinary foals. Further, Baron de Parana has for a number of years been engaged in crossing cattle and in watching the results obtained in several mule-breeding establishments, where from 400 to 1000 brood mares are kept. As in these establishments the mares breed mules and horses alternately—two or three mules and then a horse foal—there has been carried on for some years, under the observation of Baron de Parana, a telegony experiment on a gigantic scale.

The single hybrid bred by Lord Morton had extremely few stripes, and only in a remote way suggested a member of the zebra family. All my hybrids, like those bred in Brazil, have more stripes than their zebra sire, and in some of them the bands are nearly as conspicuous as in some of the zebras, thus proving that both the mares (which varied in colour and breed) and the two zebra stallions used were well adapted for the experiment. The results of my experiments, not only with the Equidæ but also with other domestic quadrupeds and birds, all point to the conclusion that there is no such thing as telegony, and the same conclusion has been independently arrived at by Baron de Parana in Brazil. Believers in telegony—they are numerous in America, India, and Australasia, as well as in England—almost always say of the many experiments recently made with a view to giving "infection" a chance of showing itself that they have only yielded negative results, and they generally add, it is impossible to prove a negative. After carefully considering all the more striking so-called cases of "infection," I have no hesitation in saying that there is no satisfactory evidence that there has ever been, either in the human family or amongst domestic animals, a single instance of infection.

I have in a hurried and imperfect manner indicated that we are not likely to find either in maternal impressions, the direct action of the environment, use-inheritance, or telegony a true cause of variation. I have endeavoured to point out that, instead of simply stating that variation is due to the constant recurrence of slight inequalities of nutrition of the germ-cells, we may with some confidence assert that differences in the age, vigour, and health of the parents and differences in the ripeness of the germ-cells are potent causes of variation.

I have also endeavoured to prove that intercrossing, though a *direct* cause of retrogressive variation, is only an *indirect* cause of progressive variation, while interbreeding (in-and-in-breeding) at the right moment is a cause of progressive variation.

Further, I have discussed at some length the swamping effects of intercrossing, chiefly with the object of showing (1) that progress in a single direction is probably often due to new varieties swamping old, it may be long established, varieties; and (2) that several varieties may be sufficiently exclusive to flourish side by side in the same area, and eventually (partly owing to their aloofness, *i.e.*, to differential mating) give rise to several new species.

I have only now to add that I was mainly led to select "The Experimental Study of Variation" as the subject of my address that I might indirectly indicate that the time had come when a well-equipped institute should be provided for biological and other experiments.

NOTES.

THE *Times* announces that the Indian Government have adopted the suggestion of the Royal Society for the carrying out of a magnetic survey. The existing magnetic observatories at Bombay and Calcutta being inadequate as base stations for the vast area the survey will cover, similar observatories are in course of construction at Dehra Dun, at Kodaikanal, and at Rangoon. The Dehra Dun observatory will be under the supervision of Colonel Gore, R.E., the Surveyor-General of the Indian Survey (whose headquarters are located there); but the other four will be in charge of Mr. John Eliot, the meteorological reporter to the Government. The Survey and Meteorological Departments will, in fact, be jointly responsible for the investigations. The field observations will be carried out by six or seven detachments of the Survey Department, and these will be controlled by Captain Fraser, R.E., who has recently been arranging in England for the purchase of the necessary instruments. Sind and the Punjab will first be taken in hand; and, as the country is now intersected with railways in all directions, enabling field detachments to quickly cover the distances from one observing station to another, it is anticipated that five years will suffice to complete the field work of the preliminary magnetic survey.

IT is stated that a committee is being formed at Amalfi to arrange for the celebration of the fourth centenary of the invention of the compass. The Duke of the Abruzzi has agreed to be president of the committee, and Signor Morin, the Minister of Marine, the vice-president. The celebration will take place next year.

To obtain information for the Lightning Research Committee organised by the Royal Institute of British Architects and the Surveyors' Institution, the Institution of Electrical Engineers has sent papers of questions to the secretaries of local branches abroad, and it is hoped that members resident in districts outside Great Britain will cooperate in the work.

THE gold medal of the Italian Science Society has been presented to Mr. Marconi in London for his services in the invention of wireless telegraphy. The medal was entrusted by the Minister for Foreign Affairs in Rome to the Marquis Luigi Solari di Loreto, an officer in the Italian navy. Count Vinci, Chargé d'Affaires of Italy in London, and Cav. P. T. Righetti, Vice-Consul, were also present. The Marquis Solari, in handing the medal to Mr. Marconi, expressed the admiration of Italy for her distinguished son, whom the whole country remembered with pride and delight. Mr. Marconi, in reply, stated that among the many marks of distinction conferred on him he prized none so much as those which came from his beloved native land.

M. SANTOS DUMONT made an ascent with his new steerable balloon on Friday last, and though he was successful in navigating the balloon, an accident occurred owing to one of the guide-ropes getting caught among some trees. He hopes to make another ascent in a week or so. The Paris correspondent of the *Times* says that the scientific committee of the Aëro Club has resolved that the competitors for the Deutsch Prize must not only return to the starting-point within twenty minutes after rounding the Eiffel Tower, but must actually touch ground in the Aëro Club enclosure. Mr. William Beedle, whose balloon is now being rapidly got ready at the Spencer Works, intends to be in Paris towards the end of October to try for the prize. He has a more powerful motor than that of M. Santos Dumont, 28-horse power, and a tougher envelope protected, and, it is believed, so arranged under an aluminium framework as to secure perfect rigidity for all practical purposes.

THE fifth International Congress of Criminal Anthropology was opened at Amsterdam on Monday last. Among the papers contributed was one by Prof. Lombroso, on the latest anatomical researches into degeneration and on tattooing.

WE regret to notice the announcement of the death, on the 7th inst., of Dr. John Louis William Thudichum, well known for his researches in organic and physiological chemistry.

THE late Mr. H. M. Courage, of Snowdenham Hall, Bramley, has left the whole of his valuable collection of birds, numbering between 6000 and 7000 specimens, to the governors of Cheltenham College. A few years before his death, which occurred last month, Mr. Courage presented a representative collection of British birds to the Hobart Museum, Tasmania.

THE Baumgartner prize of the value of 2000 crowns will be awarded at the end of 1903 by the Vienna Academy of Sciences for a research enlarging our knowledge of the invisible radiations.

Science announces that the Veitch silver medal for distinguished services in botany and horticulture has been awarded to Mr. Thomas Meehan, of Philadelphia.

THE Surrey County Council have taken a practical step in the direction of the prevention of tuberculosis by the issue of a leaflet dealing with the character of the disease, its great mortality, the manner in which it is spread, and the precautions which should be taken to prevent infection. This leaflet has been drawn up by the county medical officer, Dr. Seaton, acting on the instructions of the sanitary committee of the County Council, and local authorities throughout the county have been asked to cooperate in the dissemination of this information to every household in Surrey. The committee recommend all sanitary authorities to inform medical practitioners in their districts that, after the death or removal of a patient suffering from the disease, they will undertake disinfection of the premises at their own cost.

AN analysis of dust which fell at Fiume, Hungary, on March 10–11, and was described as showers of "red or blood rain" over a large part of Southern and Central Europe, was made by M. M. Barac, and the results are given in the number of the *Journal* of the Royal Meteorological Society just issued (vol. xxvii. No. 119). It will be remembered that some of the dust was collected by Prof. Rücker at Taormina, and described by Prof. Judd in these columns on March 28 (p. 514). M. Barac's chemical analysis gave the following percentage composition for the material:—Silica, 49·49; iron sesquioxide, 9·96; alumina, 12·10; manganese peroxide, 1·99; lime, 11·46; magnesia, 0·40; carbonic acid, 8·96; organic matter, 5·48; traces of soda, sulphuric acid, hydrochloric acid, &c., 0·16. Under the microscope, with a power of 640, M. Barac found the main mass to consist principally of colourless and, in less degree, of coloured particles, of irregular shape, partly angular fragments of crystals, and also mineral particles. In addition there were siliceous skeletons of micro-organisms, and, finally, particles of soot. There were a few well-formed rhombohedra of calcite and cubes of common salt; and both the calcite and the quartz crystals exhibited chromatic polarisation. As regards magnitude, the minimum was 0·001 mm., the average 0·017 mm., and the maximum among the crystalline particles 0·051 mm.; while the yellow structureless mineral particles attained the size of 0·113 mm.

MAJOR RONALD ROSS, F.R.S., has sent a letter to Mr. A. L. Jones giving some particulars as to the results of his visit to the Gold Coast and the work of the fifth expedition of the Liverpool School of Tropical Medicine in Sierra Leone. He says that at Sierra Leone he found Dr. Logan Taylor pushing on the operations against mosquitoes with great vigour. A report received a few days ago from Dr. Logan Taylor states that 5000 houses in Freetown have been cleared of vessels of every description which previously served as breeding places for mosquitoes. What a serious blow this will be to the prevalence of the Culex mosquito in Freetown will be readily understood. The result is already well marked, and there is undoubtedly a great reduction in the number of these insects in the centre of the town generally. Of course, the insects will still occur for some time here and there, but their breeding places can be easily detected and abolished. To judge of the value of these operations it must be remembered that besides causing constant annoyance to everyone, the insects carry the germs of yellow fever, elephantiasis, and perhaps other diseases. Operations against the Anopheles mosquito (which breed in puddles on the ground) are also being well pushed by Drs. Taylor and Berkeley. Hollows in the ground are everywhere being drained away or filled up with rubble and earth. Others are being filled with the empty bottles and tins found in the houses. Many of the worst streets, which formerly were practically marshes in the rains, have been reclaimed. Major Ross says it is now a matter of some difficulty to catch Anopheles for scientific examination, and it seems that a little perseverance will ultimately abolish these malaria-bearing insects as a disease factor in Freetown. Major Ross remarks in conclusion that the unhealthiness of the Coast has been much exaggerated. True, there is a considerable amount of malaria among Europeans; but then there is little or no typhoid. He says that in nine cases out of ten if a man contracts malarial infection it is his own fault.

THE *Pioneer Mail*, Allahabad, states that Mr. Rea, superintendent of the Archæological Survey of Madras and Coorg, has discovered a field for exploration in the Tinnevelly district which promises to be of much interest and importance. The site, which is near Adichanallar, has been, Mr. Rea thinks, at one time a very large town. "The deposits, if fully excavated, would, I have not the slightest doubt," says Mr. Rea, "stock several museums with unique objects of the most interesting description, for almost every excavation brings to light something not heretofore found. I have examined many prehistoric sites, but have never seen one so extensive and varied in its results as this. Extensive tracts are yet untouched. . . . Over 114 acres are now reserved, but the remains extend even beyond that area. It would require several years' steady work to completely explore the place. That this is by far the most important and extensive prehistoric burial place as yet discovered in Madras, I can certainly state." Some eighteen hundred curious objects in bronze, iron and pottery, as well as seven pure gold oval-shaped ornaments, have already been unearthed.

THE Grand Trunk Railway of Canada, according to the *Railway and Engineering Review*, has recently constructed, and commenced using, a car specially adapted for the distribution of live fish to waters along its lines. The interior of the car is arranged with a series of galvanised iron tanks to hold from 1000 to 1500 fish. At one end of the car is an upper and lower berth, like those in a Pullman car, to accommodate two men. Ice for keeping the water at a certain temperature is carried in two compartments built for this purpose and holding about one ton each. Arrangements have been made for replenishing the water in the tanks, *en route*, by attaching a hose to any of the hydrants at stations on the road.

THE Museum of the Literary and Philosophical Society of Hull has recently been taken over by the Corporation, and one of the first results is a note (*Yorkshire Naturalist* for August) by the Curator (Mr. T. Sheppard) on the type skeleton of Sibbald's rorqual, which forms one of the treasures of the collection. The animal to which this skeleton belonged was stranded in the Humber so long ago as 1835.

THE September issue of the *Entomologist's Monthly Magazine* contains the commencement of a series of articles on the insect fauna of the Balearic Islands, mainly based on collections made by Prof. Poulton and Messrs. Pocock and Thomas of the British Museum. Prof. Poulton himself contributes the introduction to the series, and he is followed by Mr. E. Saunders, who describes the bees, wasps, and their allies. In Majorca much of the original insect fauna appears to have been exterminated by agriculture, although much of interest will, it is hoped, still be found. In Minorca, where cultivation is not carried on to such an extent, insect life is probably much richer.

THE polychætous annelids of the Puget Sound region form the subject of a communication by Mr. H. P. Johnson published in vol. xxix. (No. 18) of the *Proceedings* of the Boston Natural History Society. Including two species from British Columbia sent by Prof. Herdman, the collection at the author's disposal comprises fifty-one species (many of which are new), classed in thirty-four genera. Nearly all the forms were collected between tide-marks, and only one is common to the Japanese coast. This latter fact is not surprising when it is borne in mind that the Puget Sound fauna is boreal, while the forms collected in Japan pertain to the Indo-Pacific fauna.

SOME time ago Prof. E. B. Poulton announced in these columns (vol. lx. p. 591) the discovery of two species of peripatus in the Siamese Malay States, this being the first record of the occurrence of this group on the Asiatic mainland. These two new forms, together with a third from Selangor, are described by Mr. R. Evans in the August number of the *Quarterly Journal of Microscopical Science*. This description has involved a reclassification of the group (Onychophora), and the author proposes the new generic title Eoperipatus for the Malayan (inclusive of the Sumatran) forms. Curiously enough, these are more nearly related to the Central American than to any other members of the group, although they are connected to a certain extent with the African forms through a species which is now assigned to a second new genus (Mesoperipatus). It is concluded that the birthplace of this very archaic group was probably Africa. In another article in the same journal Mr. S. B. Mitra, of Calcutta, discusses the function of the so-called "crystalline style" of the bivalve molluscs. After reviewing previous theories, the author comes to the conclusion that this remarkable rod-like body (which in the common pond-mussel is three-fourths the entire length of the animal) really acts as a digestive ferment whose function is to convert starch into sugar.

THE services which anthropometry renders to physical education are dealt with by Major Dr. Paul Godin in the *Bulletins et Mémoires* de la Société d'Anthropologie de Paris (5e série, tome ii. 1902, fascic. 2, p. 110), whose paper is fortified by numerous tables and graphic curves.

THE development of illumination, or rather the evolution of artificial illumination, is the subject of a short paper by Mr. Walter Hough in the *American Anthropologist* (N.S., vol. iii. 1901, p. 342), in which he epitomises the stages in the development of the candle and of the lamp. It is only comparatively recently that the latter has improved beyond a very simple and inefficient contrivance; at present the destiny of illumination is in the hands of the investigator and inventor.

UNDER the title of "Les Peuplades de Guinée" (*Revue Scientifique*, 4e Sér. T. 16, No. 8, p. 233), M. A. Vergely gives an account more particularly of the Soussous (Susu), who he thinks have been greatly calumniated. He describes their appearance, mental traits, clothing, mode of life, morality, and other social characteristics, and contrasts with them the Foullas (Fulah); the former are true negroes, the latter are Hamites. This comparison of two very different people living under the same conditions is very suggestive.

THERE have been several theories for the origin of the word "Surrey." Mr. T. le Marchant Douse, in the *Home Counties Magazine* (vol. iii. No. 11, July 1901, p. 198), follows up the suggestion of Kluge, and produces an array of evidence that supports his contention that it means the land of the South Rige, who are identified with the Rugii of Tacitus. The oldest known habitat of the Rugi was by the mouth and lower course of the Oder, probably to the east of it. Very early in our era the Goths wholly or in part dispossessed them; some migrated southward, others westward and north-westward, and it is extremely probable that the Baltic Rugi in the fifth century joined other adventurers, but under their own chief or king, and settled in England. Surrey continued to be called a "kingdom" long after it had ceased to have a king to itself. Eastry, near Sandwich in Kent, is now a large village and parish, but was formerly a town and district; in a charter of 788 this is spoken of as "the district of the Eastriges."

IN the current number of the *Bulletins et Mémoires* de la Soc. d'Anthropologie de Paris (5e série, tome ii. 1902, fascic. 2) there are two illustrated papers, by Dr. Atgier, on deformed heads of living subjects: the one is a case of oxycephaly or acrocephaly and the other of scaphocephaly. The discussions on these cases is as important as the original papers. M. Pelletier proposes (p. 188) a new method of obtaining the cubic index of the skull. It is sometimes impossible to measure the cubic capacity of a skull by the ordinary methods, and always to do so in the case of the living, so recourse has to be made to an estimation of the capacity from certain measurements. Those in vogue are the glabella-occipital length, the greatest breadth and the basio-bregmatic height. The author proposes the ophryo-occipital length, the greatest breadth and the auriculo-bregmatic height; for, as he justly observes, these can also be made approximately on the living. We are glad to find that the auricular height, which has been employed by one or two British anthropologists, is recognised as of more value than the basial height. Those who are interested in this subject should also consult the recent noteworthy investigations by Alice Lee and Karl Pearson on the determination of capacity of the human skull from external measurements (*Phil. Trans. Roy. Soc.* series A, vol. cxcvi. pp. 225-264, "Data for the Problem of Evolution in Man; vi. A First Study of the Correlation of the Human Skull").

AN appreciative article on the life and work of Prof. T. G. Bonney, F.R.S., appears in the September number of the *Geological Magazine*, being the first of what is apparently to be a series of biographies of eminent living geologists. The article is accompanied by a portrait of Prof. Bonney, reproduced as a full-page plate.

THE first part of a work on European butterflies—"Die Schmetterlinge Europas"—by Dr. A. Spuler, forming the third edition of E. Hoffmann's treatise, has been received. It is intended to complete the work in thirty-eight parts, which together will contain descriptive text and nearly a hundred plates having about 2700 coloured pictures of butterflies upon them. The book will be noticed when all the parts have been received. Messrs. Heyne Brothers are the English publishers.

THE Annual Report of Mr. J. C. Smock, the State Geologist of New Jersey, contains important articles on the Portland Cement Industry and on the Iron and Copper Mines by Dr. H. B. Kümmel, and on Artesian Wells by Mr. Lewis Woolman. One boring in Atlantic City has been carried to a depth of 2285 feet, and is still being drilled; so far without success. Mr. W. S. Myers contributes a short article on Chlorine in the Natural Waters of the State, and draws attention to its importance in the examination of waters suspected of contamination by sewage.

THERE is an interesting sketch of the vestiges of the ancient settlement of the Northmen in the Isle of Man, by Anton Weis, in *Globus* (Band lxxx. No. 7, p. 113), but the author makes a remarkable slip when he states that "this little island is only four to five miles long and two miles broad."

THE additions to the Zoological Society's Gardens during the past week include a Jaguar (*Felis onca*, ♀) from South America, presented by Mr. F. W. Barrow; a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, presented by Mr. A. N. Owen; an Egyptian Jerboa (*Dipus aegyptius*) from Egypt, presented by Miss A. Moore; a Tawny Owl (*Syrnium aluco*), British, presented by Mr. T. E. Gunn; a Green Turtle (*Chelone mydas*) from the Tropical Seas, presented by Captain Stevenson; a Madagascar Tree Boa (*Corallus madagascariensis*), a Madagascar Boa (*Boa madagascariensis*), eight Sharp-headed Snakes (*Lioheterodon madagascariensis*) from Madagascar, a Chameleon (*Chamaeleon vulgaris*) from North Africa, deposited.

OUR ASTRONOMICAL COLUMN.

OPPOSITION OF EROS IN 1903.—The planet Eros has now so nearly approached the sun that further observations of its light have become impossible; but as the amount of material accumulated since the discovery of its variability in brightness is not sufficient for determining satisfactorily the laws governing it, full advantage of all the future opportunities of observing the body should be taken.

Since three times the tropical period is about seven years, the favourable conditions of 1893 and 1900 will not be repeated until 1907. The coming opposition in 1903 will be similar to that of 1896, and although not specially favourable, may possibly give opportunities for useful measurements. With this end in view, Prof. Pickering has issued an ephemeris showing the computed path of the planet during the years 1901, 1902 and 1903, the accidental errors of which have been eliminated as far as possible. The magnitudes given are not corrected for phase, and are based on the assumption that the magnitude at unit distance = 11·39. From these tables it appears that the next most favourable time of observation will be during the spring of 1903, and preparations are being made for an extensive series of photometric measures at Arequipa during that period. (*Harvard College Observatory Circular*, No. 61).

RADIAL VELOCITY OF 1830 GROOMBRIDGE.—An interesting investigation is reported by Prof. Campbell, bearing on the spectroscopic determination of the velocity in the line of sight of 1830 Groombridge, the star which, until lately, had the largest known proper motion (7″·05 per year). Although the various determinations of the parallax of this star differ somewhat in value, they all agree in placing the star at a great distance, Newcomb's adopted parallax being 0″·14. Assuming this as the true value, the component of the star's velocity *perpendicular* to the line of sight will be 240 kilometres (150 miles) per second. The component of its velocity *in* the line of sight has been determined from *four* photographs of its spectrum taken with the Mills spectrograph; the results from all are substantially in agreement; the best values are :—

Date.	Velocity. Kilometres.	Miles.
1901 March 18	−93	−58
April 1	−97	−60

The mean value of the radial velocity is taken as -95 ± 5 kilometres per second (equivalent to 59 miles per second approach). The spectrum is approximately of the solar type, inclining rather to the characteristics of Procyon or α Persei. The best photograph was obtained with an exposure of two hours (*Lick Observatory Bulletin*, No. 4).

NOVA PERSEI.—MM. Flammarion and Antoniadi give some further particulars in the *Astronomische Nachrichten* (Bd. 156, No. 3736) respecting the peculiar appearance of the Nova. The photographs of the star region were obtained with an Hermagis photographic objective of 16 cm. aperture and 70 cm. focal length.

Three proofs on paper have been examined, both enlargements and direct prints. That from the plate obtained on August 19, with an exposure of 30 minutes, shows that the image of the new star is very different in appearance to the images of neighbouring stars, being surrounded by a strong penumbra with a sharp edge, the mean diameter of which is about 2′ of arc. Another from a negative which was exposed for a much longer period, 3h. 20m., shows the image of the star encroaching on the first penumbra, but beyond this there is shown a much larger aureole, some 6′ of arc in diameter, and the appearance is said to resemble the umbra and penumbra of a sunspot.

VARIABLE RADIAL VELOCITY OF δ ORIONIS.—The variable velocity of this star was discovered by M. Deslandres from observations made with a spectroscope attached to the great Meudon refractor. The star is not quite suited for this type of investigation, as the lines are broad, but three observations secured during 1900 confirm M. Deslandres' results.

The velocities reduced from these were :—

1900 August 12	+3	kilometres per sec.
" 21	+51	" "
Sept. 17	−69	" "

(*Lick Observatory Bulletin*, No. 4.)

IRON AND STEEL INSTITUTE.

THE autumn meeting of the Iron and Steel Institute was held on September 3 and 4, in conjunction with the International Engineering Congress, at the University of Glasgow, and was very largely attended. After speeches of welcome, the president, Mr. W. Whitwell, delivered a short introductory address, in which he dwelt upon the advantages to be expected from the fact that the Iron and Steel Institute met for the first time in its history in conjunction with eight other societies, forming one great International Engineering Congress. In the overwhelming mass of matter published by these societies there was, he considered, a certain amount of overlapping that the Congress might tend to obviate in the future. Some of the papers, too, at first sight might appear to be of little practical importance. This criticism had frequently been applied to many of the papers read before the Iron and Steel Institute. It must be remembered, however, that this had been from time immemorial the favourite objection to the work of pioneers of thought.

The 30,000 pages published by the Iron and Steel Institute since its inauguration in 1871 afforded fruitful examples of the subsequent value of scientific researches, which, when first presented, were received with coolness and suspicion. Numerous examples might be cited. For instance, the microscopic method of investigating the structure of steel, created by Sorby, Martens, Osmond, Howe and Stead, had become an indispensable auxiliary to chemical analysis and physical tests in steelworks. The abstruse memoirs on the heat treatment of steel, and on pyrometry, had led to important practical applications, and the phase rule enunciated by the American professor, Gibbs, and applied by Sir William Roberts-Austen, Baron Jüptner, Le Chatelier and Stansfield would no doubt eventually prove of extreme value in elucidating some of the more intricate problems confronting the metallurgist.

The first paper was read by Mr. Walter Dixon. It contained a concise account of the iron and steel industries of the west of Scotland, drawn up by a committee of the local metallurgical society, pig iron being dealt with by Mr. Henry Bumby, wrought iron by Mr. W. Wylie, and steel by Mr. H. Archibald.

The second paper was also the report of a committee, presented by Mr. Bennett H. Brough, the secretary. In view of the fact that with the development of metallography the nomenclature was becoming more and more involved, the Iron and Steel Institute appointed a committee to consider the matter and to ascertain whether it would be possible to take steps to make the terminology less complicated and more precise. A glossary was submitted, containing the more important terms used by authors of memoirs dealing with metallography, in the hope of obtaining criticisms and suggestions in order that the committee might have before them data upon which to base their judgment. In each case the equivalents in French and German were added.

Mr. A. Wahlberg (Stockholm), then read a paper on variations of carbon and phosphorus in steel ingots. The object of his research was to establish the limits of variation of carbon and phosphorus in steel which has been cast into 10-inch ingots and then rolled into 4-inch billets, and to ascertain to what extent chemical analyses of identical samples vary in their results as regard the percentage of carbon and of phosphorus when made by different chemists. The material tested was procured from four works and was analysed in four laboratories. The variation in chemical composition in different portions of the billet and the divergent results obtained by different analysts were well shown in a number of tables. In the discussion which followed the reading of the paper, the need for standard methods of analysis was urged.

The meeting then adjourned until September 4, when Mr. C. H. Ridsdale read a lengthy paper of great practical interest on the correct treatment of steel. After a full discussion of this paper, Mr. J. E. Stead read an abstract of two papers. In the first, on copper and iron alloys, he reviewed the contradictory evidence in metallurgical text-books, and gave the results of his recent work. Copper and iron, he showed, alloyed most readily by direct fusion in all proportions. Such alloys might be classed in three main sections: (*a*) with traces to 2·73 per cent. of iron and 97·2 per cent. of copper, (*b*) with 8·0 per cent. of copper and 91·5 per cent. of iron, and (*c*) alloys intermediate between the two. The alloys of the first two sections are practically homogeneous, class *a* consisting of copper with iron in solid solution and class *b* consisting of iron with copper in solution. The alloys of the third class contain saturated solid solutions, copper in iron and iron in copper, separate from each other but in micro-juxtaposition. In solidifying the portion first to fall out of solution was the iron containing copper in solid solution. The conflicting character of evidence previously published was probably due to the fact that some of the investigators in the past had not taken the precaution to use iron free from carbon. The effect of carbon is marked. On heating the alloys containing more than 7·5 per cent. of copper to whiteness with charcoal, copper containing about 10 per cent. of iron is thrown out of solution and falls to the bottom, leaving a layer of carburised iron on the surface containing about 7·5 per cent. of copper.

In the next paper, Mr. J. E. Stead and Mr. F. H. Wigham described experiments on a series of steels with and without copper prepared by dividing the finished steel in each series when in a fluid state into two parts, to one of which copper was added in amounts varying between 0·46 and 2·0 per cent. Elaborate tests showed that copper in such large quantities does not improve the quality of the wire, but generally has a deteriorating influence, particularly in the presence of high carbon. The only good property exhibited by cupreous steel wire is that it resists corrosion.

Mr. G. Watson Gray then read a paper recording the occurrence of calcium in a ferro-silicon. He gave analyses of ferro-silicons containing 0·79 to 14·40 per cent. of calcium, and described a new method for the analysis of ferro-silicon.

A lengthy paper on the profitable utilisation of power from blast-furnace gases was read by Mr. B. H. Thwaite. One of the results following the use of blast-furnace gas for the direct production of power in internal combustion engines has been marked progress in the mechanical perfection of power capacities and in the thermodynamic efficiency of this engine. A new scheme for obtaining all the power possible from the blast furnace, devised by the author, includes the recovery of the sensible heat that is otherwise lost in cooling the blast-furnace gases, in heating the air to convert coal into gas in producers, and in supporting the combustion of the gases thus produced in hot-blast stoves. The various outlets for electric power that could be generated by the new system are described. The production of silicon and calcium carbides, of chromium, nickel and aluminium are instanced as being exceptionally suitable as associated industries for ironworks.

Prof. W. N. Hartley and Mr. H. Ramage next gave the results of an investigation of the spectra of flames at different periods during the basic Bessemer blow. The conclusion arrived at was that the phenomena of the basic Bessemer blow differ considerably from those of the acid process, in the following respects:—

First, a flame is visible from the commencement of blowing, or as soon as the cloud of lime dust has dispersed. We conclude that the immediate production of this flame is caused by carbonaceous matter in the lining of the vessel, that its luminosity is due partly to the volatilisation of the alkalis, and to the incandescence of lime dust carried out by the blast.

Secondly, volatilisation of metal occurs largely at an early period in the blow, and is due to the difference in composition of the metal blown, chiefly to the smaller quantity of silicon. There is practically no distinct period when siliceous slags are formed in the "basic" process, and metals are volatilised readily in the reducing atmosphere, rich in carbon monoxide.

Thirdly, a very large amount of fume is formed towards the close of the second period. This arises from the oxidation of metal and of phosphorus in the iron phosphide being productive of a high temperature, but little or no carbon remaining. The flame is comparatively short, and the metallic vapours carried up are burnt by the blast.

Fourthly, the "over-blow" is characterised by a very powerful illumination from what appears to be a brilliant yellow flame; a dense fume is produced at this time composed of oxidised metallic vapours, chiefly iron. These particles are undoubtedly of very minute dimensions, as is proved by the fact that they scatter the light which falls on them, and the cloud casts a brown shadow, and, on a still day, ascends to a great height. In a given flame the brilliancy of the line spectrum of potassium is increased by diminishing the quantity of metallic vapour in the flame; this does not appear to depend altogether on the weakening of the continuous spectrum which accompanies the line spectrum of potassium; some experiments made with various salts of potassium show that it is probably due, in part at least, to the increased freedom of motion permitted to the molecules of the metal.

Mr. A. Wahlberg (Stockholm) submitted the second portion of his elaborate memoir on Brinell's method of determining hardness and other properties of iron and steel. The first portion was read at the May meeting, and the two together constitute a monograph of about one hundred pages. The second portion dealt more particularly with the influence of different methods of annealing and hardening on the tensile properties of iron and steel determined by means of tensile tests, and with researches undertaken for the purpose of ascertaining the influence of chemical composition and various modes of treatment on the resistance to impact in iron and steel at ordinary and low temperatures.

Mr. Arthur Wirgham submitted a very suggestive paper on the internal strains of iron and steel and their bearing upon fracture.

The object of the paper was to assist the elucidation of some of the mysteries attendant upon the physical behaviour of metals generally, and of iron and steel in particular, and to throw light upon the cause of the sudden and unexpected breakages of metal used for machinery and other purposes. Its reasonings were based upon the following facts and hypotheses:—That there are two kinds of equilibrium to which a metal attains, viz., chemical and physical; that the natural tendency of a complex metal is to assume its most simple forms of combination preferentially capable of existing at a given temperature; that its rapidity of cooling, even under the slowest conditions, is too great to allow this to reach finality; that the equilibrium is further repeatedly interfered with by changes of atmospheric and other conditions; that the adjustment to physical equilibrium tends to assist the adjustment to chemical equilibrium; that adjustment which is assisted by slightly raised temperatures, also, as a consequence, takes place in the cold; and that the eutectic is the medium through which the chemical or molecular change takes place, working, of course, in conjunction with the vibration of the molecules.

RELATIONS BETWEEN CLIMATE AND CROPS.[1]

THE weather exerts a tacit, though relentless, tyranny over the labour and the thought of the agriculturist. The probable influences of the present and prospective weather upon the growing crops are seldom absent from his mind. But science teaches that climate is rhythmic, not capricious. Laplace has shown that the mean temperature of the mass of the earth cannot have changed in any appreciable measure during the entire period of astronomical calculation, and that while the planetary movements remain as at present no such change can occur. "Astronomical permanency," he says, "implies an absolute fixedness of the quantity of heat for the mass of the earth." And the sun's heat is the leading element of climate; all other conditions depend in the long run upon that. Hence, the sun's heat being constant, all the changes we observe are periodic as regards the astronomical units, the day and the year; and non-periodic in all other cases, the averages returning always to a line of absolute permanency.

Climate is the average of seasonal atmospheric conditions, and as corn is an annual plant, these fluctuating seasonal factors must affect its growth. The crop season is in fact the climatic unit with respect to this cereal. No season exactly repeats itself; there are perturbations within relatively narrow limits; the plant strives perpetually to adjust itself to perfect correspondence with its environment. As this environment—that is, climate and food supply—vibrates now one way, now another, about a fixed mean, the consequent variations of the plant will be compensatory, and so there should be no final permanent modification of the plant in a given locality.

Aside from its direct control of the amount and quality of the crop, climatic variations, by vitiating experience, impede agricultural progress. This fact is most apparent in the agricultural history of a new country, where experience acquired in one district is in many cases not only useless, but positively pernicious, when applied to a distant district. In the United States millions of dollars have been lost through the efforts of new settlers to learn by experience the climatic peculiarities of their adopted home. It is the province of agricultural science to teach how to profit by the experience that has been so dearly bought in the past.

Agricultural climatology considers the relations between the meteorological elements measured in terms of plant development. As intimate as these relations are known to be, and as interesting and promising a field as their study is known to offer, it is rather surprising that no adequate organised effort has yet been expended in this direction. But we are coming to see that the very fact of this intimate reciprocal dependence may be turned to advantage, and that by methods of correlation the facts of each science may be made to illumine the other.

The laws of biological and of meteorological phenomena separately considered are extremely subtle and complex, and any attempt to study them in their manifold reciprocal relations is sufficiently difficult to deter any but the best equipped and most zealous students. This difficulty of properly interpreting the separate effects upon vegetation of heat, light, moisture, and the gases of the atmosphere is enhanced by the fact that a change in one meteorological condition ordinarily disturbs all the other elements. For example, rain is accompanied by cloudiness, decrease in light and heat, and, it may be, by an increase of warmth in the soil, if the rain be a warm one.

Extended and elaborate meteorological observations have been conducted in the United States and in Europe, but instruments measure only detached elements of climate; plants alone record its composite or cumulative effects. Hence, the insistence on the part of leading agricultural investigators that climate should be studied in terms of plant life. Such study is termed phenology, and while it has led to some valuable generalisations, the fragmentary character of the data vitiates many of its conclusions. It appears that in the past phenologists have given the element of heat undue, if not almost exclusive, weight. It is becoming more and more evident that the real function and value of light have been neglected and undervalued. A fundamental theory which has been held by botanists for more than a century is, briefly, that a certain life event takes place in any species whenever that species has been exposed to a certain sum total of heat, which is called the physiological constant or thermal constant. In harmony with this theory, Blodgett, in his "Climatology of the United States," says with regard to corn that its period of growth is precisely proportional to the abruptness of the temperature curve; that its unusual elasticity of constitution admits it to all regions where the temperature reaches a certain point, however brief the duration of this warm period may be. He defines the extreme northern limits of Indian corn as coincident with the isotherm of 67° for July, though a somewhat higher mean for one summer month is required, and he attributes the increase of productiveness at the north mainly to "the hasty growth, the excess of heat while it lasts, and the hastened ripening period." The seemingly insignificant item of a deficiency of two degrees on the mean of a single summer month practically excludes this crop from the British Isles, where it is grown, when grown at all, only as a forage crop, seldom maturing any grain. This statement of the subject has been for fifty years the popular and the current theory. Temperature being the most easily measured of the solar manifestations, it has quite naturally been regarded as the dominant one. Then, too, the rudimentary state of climatology made necessary such a simplification as is afforded by the consideration of heat alone.

The trend of recent opinion is summarised by Prof. Abbe in his extensive manuscript report of June 1891, on the "Relations of Climate and Crops," where, after reviewing the investigations of Tisserand, he concludes:—

That the temperature of the air has apparently little to do, in and of itself, with the duration of time from sowing to ripening, but that this depends principally on the sunshine. The temperature of the air controls the chemical composition of the seed, but the effective sunshine seems to be the productive climatic element; it furnishes the total energy at the disposal of the plant, but it is also the one least studied and understood.

Prof. Sturtevant, of New York, from tests with 128 varieties, concludes that "actinism has an influence scarcely secondary to temperature." So it would seem wise in the light of recent study to attribute much of the hostility of a climate like that of England to the greater degree of cloudiness, and the congeniality of the climate of the Western States to the habitually clear skies of summer.

In discussing climate and corn it will be convenient to treat their relations first historically and then analytically; a cursory glance at the more evident accumulated results of climatic modification and limitation will prepare the way for an outline of the individual factors that constitute environment and the principles that govern the life of the plant.

The original home of corn or maize is now quite certainly known to have been in Central Mexico, and hence it is the only one of our cereals that is indigenous to the New World. It has been so long and so thoroughly domesticated that no truly wild varieties are known. In geographical range and elasticity of habit it probably surpasses every other cultivated plant. From its original tropical home it has spread to the temperate as well as the tropical regions of the world. Introduced into

[1] Abridged from a paper by Mr. H. B. Wren in the U.S. *Monthly Weather Review.*

Europe soon after the conquest of Mexico, it finds a genial home only in the warm valleys of the south and central portions of that continent; it is extensively grown in Africa, and in India it thrives everywhere throughout the hill country; it appears to flourish as well in the temperate as the tropical regions, and at altitudes of from sea-level to 7000 feet or more. Corn is, however, as it has always been and will undoubtedly remain, a distinctive and characteristic American product. It is cultivated from Canada to Patagonia, over 7000 miles of latitude. It has been known to ripen as far north as 63°, and has been found a profitable crop in latitude 51° north. In response to the multifarious conditions which this great range imposes, countless varieties have been developed, there being more than 200 in the United States alone.

The effects of climate on maize may be appropriately classified as immediate, intermediate, and incidental. Prof. Storer has tersely said that the prime object of agriculture is to collect for purposes of human aggrandisement as much as may be possible of the energy that comes from the sun in form of light and heat. Now the working capacity of sunshine is, according to Kelvin, one horse-power for every seven square feet of surface. Measured by the standards of mechanics, how inefficient and wasteful an engine is our agriculture at its best. The atmosphere is directly the source of 95 per cent. of the material in the total plant and of 98 per cent. of the matter in the grain of corn. The plant is an elaborate machine that absorbs and transforms energy, utilising solar radiation to digest carbon dioxide in the leaves and to combine into vegetable organs and tissues the gases of the air with the elements supplied by the soil. When we remember that the amount of energy available, the food supply, and, consequently, the amount of matter stored, all depend directly upon meteorological conditions, we realise how overwhelming is the influence of climate.

A grain of maize once matured is as inert as a pebble until heat and moisture are applied; then a sprout and a root appear, each for a separate function, the one for absorbing ethereal waves, the other for absorbing water. In addition to heat and moisture, oxygen is absolutely essential to germination, as well as to all subsequent growth. The importance of moisture will be appreciated when we recall that water performs at least four distinct offices: first, directly as a food, being united in the leaves with carbon to form the carbohydrates; second, as a solvent for the nutritive matters in the soil; third, as the vehicle which transports the soluble food through the roots and stems to the leaves; and, finally, as a cooling device, since, through evaporation, water largely controls the temperature of the plant. The "free water of vegetation," as it is called, or the water of the juices, comprises from 70 to 90 per cent. of corn in the fodder stage, while the "combined water of vegetation," or the water that remains after the plant is air-dried, is 12 per cent. in a kernel of corn.

The immediate effects of climate will be better understood by glancing first at its intermediate effects through the medium of the soil and through the food-supply. Climate originates soil and all the capacities of the earth for tillage, and it is at the same time more than soil or tillage. For in a truly "good year" the worst tilled soil returns a more bountiful harvest than it is possible with all our industry to extort from the best tilled soil in a "bad year." The oasis differs from the desert only in the item of water supply, and a given climate does not result primarily from the nature of the earth's surface; on the contrary, that surface is determined almost wholly by climate. The agencies that produce, and are producing arable areas from the seemingly impervious and indurate rocks, must continue their action perennially if the soil is to maintain itself. Indeed, the reverse metamorphosis is constantly at work. The greater part of the known rock formations were once in the form of soil, and chemical, physical, and even vital forces are continually engaged in the work of rock making, as well as rock breaking, so that an important office of agriculture is to oppose this cyclic law of nature, and to counteract the retrogressive tendency from soil to rock.

Primarily, the soil is a reservoir of moisture and plant food; but hardly secondary is its office as a vast laboratory, wherein during the warmer seasons countless complex chemical agencies and numberless microscopic organisms operate unceasingly. Indeed, the relations of climate to the plant through the medium of the soil are so intimate and vital that no just idea of their importance can be given here. These relations may be classed as physical, chemical and biological.

The physical texture of the soil determines its conductivity for heat and its content of water and air, both of which in proper proportions are essential to the chemical and biological functions. Moreover, the water content, through its power to absorb, transform, and conserve radiant energy, controls the temperature of the soil. Finally, soil temperature is far more effective than the temperature of the air. Heat is well known to accelerate diffusion, solution, osmotic action, and evaporation. Now these physical processes are precisely those that perform the chief, almost the entire work involved in plant nutrition and growth. Hence, a high soil temperature is essential not only for the life of the plant itself, but also for the ventilation and the life of the soil, a healthy soil being very appropriately called a living mass. On an average 40 per cent. of the radiant energy incident on the soil is absorbed, conducted downward, and stored in the form of heat, 60 per cent. being lost to the soil by reflection, radiation and evaporation.

Oxygen is as indispensable to the chemical life of the soil as it is to animal life. Both oxygen and nitrogen are essential to the biological processes, and both the chemical and biological activities in the soil are as indispensable to the crop as are sunshine and showers.

The importance of right proportions of water and air in the soil is further shown by the fact that the process of decay, whereby organic material is turned into humus and made available to the plant, cannot go on without an abundant supply of oxygen. A soil that contains too much water contains too little air. The ferments thrive best at a temperature of 85° to 95°, and when the soil contains from one-half to one-third the amount of water required for saturation. The ultimate source of the nitrogen found in vegetable matter is the air, and plants are unable directly to utilise it in a free state. The bacteria, which are chiefly concerned in maintaining the available supply of nitrogen in the soil, are able to work only during the warm seasons, and their activity depends directly on the temperature of the soil, being a maximum at 98°. On the other hand, light is inimical to the life and activity of these soil bacteria, a fact that may have some bearing on the rapid growth of corn during hot nights, inasmuch as the work of the micro-organisms in feeding the roots is then facilitated. That corn germinates best at the high temperature of 98° to 100° is, undoubtedly, due to its tropical origin. For Prof. Davenport shows that the attunement of plants to environment as regards temperature has its origin, not in processes of selection, but in the modifications of protoplasm by temperature itself.

Granted that the soil is porous enough and dry enough to admit the air readily, ventilation is facilitated by the unequal heating of night and day, and by non-periodic temperature changes as well. As the air within the soil is heated it expands, and some of it is forced downward to the deeper layers; when it cools it contracts, and free air is drawn into the soil. The same effect is produced by barometric changes; the passage of areas of high and low pressure has been found to influence the flow of water from drains to the extent of 15 per cent., thus showing an unexpected movement of air in the soil. The corn belt lies entirely within the region of maximum frequency and intensity of barometric oscillations in the United States. Strong, and particularly gusty winds, by a measurable aspiratory action, have also a significant influence on soil breathing.

Having seen how heat, light, moisture, and the supply of gases operate to control the supply of those ingredients that are furnished by the soil and that constitute in the main the ash of the plant, we return now to the immediate effect of these elements on the vital processes and assimilation.

While light is indispensable to the assimilation of carbon dioxide, it undoubtedly exerts a directly retarding influence on growth proper, or cell multiplication, but the beneficial effects of the higher temperature that accompanies daylight more than counteract this. Sachs showed that for many plants, when kept at a uniform temperature, the rate of growth gradually increases during the night and is a maximum shortly after daybreak. This effect of light is opposed to the effect of the diurnal temperature; heat and light increase transpiration, which means a loss of water, and hence less growth. This sensitiveness and response of protoplasm to light is the result of the chemical changes wrought therein by the light.

By osmotic action the root hairs imbibe the liquid food that surrounds them; capillary and osmotic actions carry this supply to every part of the plant, to the tip of every blade, which is not only bathed in air, but has its microscopic interstices permeated with it. Here, in the leaf cells, the carbon dioxide of the air, which is practically an invariable quantity, comes in contact with the water that has been brought from the roots. Here, too, the energy of the ether waves, which we call light, but which the vegetable cell recognises only as force, or a mode of motion, causes the carbon dioxide to part with some of its oxygen in exchange for some of the hydrogen contained in the water. Thus, there is formed within the cell a substance composed of carbon, hydrogen, and oxygen, the exact molecular structure of which is not known; in this process some of the oxygen is freed and thrown off by transpiration. By the introduction of the molecule of carbon dioxide into the cell the equilibrium in the atmosphere of that gas is disturbed and another molecule diffuses into its place; for this gas exists and behaves as if it were the only gas present in the space under consideration, the same law being true for each of the gaseous elements whose mixture constitutes what is called the atmosphere. The consumption of carbon dioxide tends constantly to produce a vacuum in the carbon dioxide atmosphere, and the law of diffusion as constantly tends to maintain the supply. If molecules of hydrogen are withdrawn from the fluid contents of the cell, instantly osmosis and diffusion tend to replace them; the same is true of the solid particles in solution. Assimilation within the cells of the leaves perpetually destroys the equilibrium of osmotic pressure, hence this pressure creates a constant flow toward the seat of demand. Evaporation from the leaves, which is proportional to temperature and is accelerated by winds, as is the supply of carbon dioxide, operates in the same direction, viz. to destroy the equilibrium in the leaf cells and channels, and consequently the tiny streams from the rootlets are hastened onward with their precious stores of food. Cold not only stiffens the sap and retards its flow, but also slackens molecular motion and hinders the chemical reorganisation of the elements. The process of evaporation proper is, however, almost independent of the processes of nutrition, and is rather a "necessary evil." The most rapid growth frequently occurs under precisely those conditions that make evaporation least rapid.

The quantity of water that passes through the plant and is transpired and evaporated is enormous. The average is about three hundred parts of water to one of dry matter. According to experiments by Prof. King of the Wisconsin Experiment Station, dent corn used three hundred and ten tons and flint corn two hundred and thirty-four tons of water for each ton of dry matter produced. This same experimenter supplied growing corn with water as fast as it could be used to advantage, and found that the crop consumed during its season of growth water equivalent to a rainfall of 34·3 inches, and yielded more than four times as bountifully as a very large crop grown under the best natural conditions of rainfall in Wisconsin. And he concludes that "large as this movement of water is, it is seldom great enough to enable a moderately fertile field to produce its largest crops." And these tests in Wisconsin merely confirm a conclusion that is becoming quite general, and is prompting the advocacy of irrigation even in the humid regions. Moreover, the quantity of water producing a given result increases with the fertility of the soil, and, according to Wollny, the soil moisture produces its maximum results only when the plants are grown in the strongest light. The value of a given quantity of rainfall for the crop increases as the number of rains, and what has been called the useful remainder of rainfall is only 20 per cent. of the total amount, percolation and evaporation accounting for 80 per cent. Percolation is a fertile source of loss of the valuable soil nitrates, especially in the wet fall and winter seasons, when the corn-field is bare and a large proportion of the water escapes downward. Rain, like snow, is the "poor man's fertiliser," bringing down, per acre, in the course of a year, at Rothamsted, England, twenty-four pounds of salt, four and a half pounds of nitrogen, eighteen pounds of sulphuric acid, and much carbon dioxide, which is a valuable solvent.

Some of the less important incidental relations of climate and corn, such as electricity, winds, frost, insect enemies, and diseases remain to be mentioned. Electricity artificially applied to the roots by charging the soil, and to the leaves by means of the electric light, have both repeatedly been found to stimulate the growth, and, in some instances, greatly to accelerate it. Recent experiments show that when green leaves are exposed to direct sunlight there is developed a difference of electrical potential between the illumined and the shaded surfaces, amounting in some cases to ·02 volt, but the bearing of this fact upon assimilation is not well known. Atmospheric electricity is a fertile source of ozone, or condensed oxygen, which is particularly active in the production of nitric acid. Electricity stimulates protoplasm, the ultimate vital principle, and may determine the character of its activities, but under natural conditions this element is believed to have but slight influence.

Seasonal characteristics have practical connection, too, with the insect pests and diseases of corn. Not only during the crop season are these pests largely at the mercy of the elements, but fitful winters are sure to prove destructive to them, for during the bright, warm days eggs are hatched, chrysalides matured, and insects lured from their retreats, only to be caught and destroyed by the sudden cold waves. The fungus diseases, such as rust and smut, are carried by winds, and are favoured by wet seasons, dews, and moist atmosphere.

So sensitive is the plant to the changes of climate that even the ordinary seasonal irregularities have a strong influence; the general disposition acquired by the seed in a single dry or wet, warm or cold, early or late, season prepares it by virtue of that experience to become the best seed for planting in anticipation of another such season as that in which the seed was matured. This tendency is illustrated by the well-known fact that dwarfed varieties of corn from northern latitudes, when cultivated to the southward, mature earlier, are hardier, and more prolific than the native varieties. A corollary of great practical promise is that in a region habitually or frequently dry, corn raised in the driest years should be preserved for seed, as likely to be far better than any that may be brought from a distance. Hence the common, if not universal, practice of using seed grown in the preceding year is strongly condemned. By always utilising seed that has been raised in the driest years one may hope speedily to develop varieties whose vegetating period will be so short that the crop will rarely be injured by the hot winds of July or August. And a similar rule would apply for any desired disposition we may seek to impress upon the seed.

In the light of these facts it is suggested that irrigation may come to be used as a temporary device to promote the evolution of new varieties that can be cultivated without irrigation. On the other hand, recent careful work in France has demonstrated that when the plants are forced to their maximum yield by irrigation the seed thereby suffers a marked deterioration, and that for continued maximum results the seed must be raised on dry soil.

Climate being inviolable and inexorable, what hope is there that the agriculturist shall be emancipated from the tyranny of frost and drought? Clearly, he must attain this by work on the soil and on the plant. By utilising vast stores of energy in the form of fuel man banishes the rigours of winter, thus creating artificial conditions of shelter and heat, by aid of which he has supplemented the process of acclimatisation. Thus, also, must he co-operate with Nature in behalf of the plant: he must combat her malignant aspects by intelligent selection; by scientific methods of culture he must supplement her beneficent efforts on behalf of the human race.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. J. W. BULLERWELL, assistant lecturer at the Durham College of Science, Newcastle-on-Tyne, has been appointed assistant lecturer in mathematics at the Hartley College, Southampton.

FOLLOWING the usual custom, addresses will be given at many of the metropolitan and provincial medical schools, at the opening of the new session early in October. At St. George's Hospital an introductory address will be given by Dr. P. W. Latham, of Cambridge. The first meeting of the Physical Society of Guy's Hospital will be held on October 5, in the new physiological theatre, when Sir Samuel Wilks, F.R.S., will preside. At St. Mary's Hospital the session will begin on October 1 with an introductory lecture by Dr. William Hill. The session at the Middlesex Hospital will also begin on October 1, when Mr. T. H. Kellock will give an introductory address. The session of the Faculty of Medicine of University College will be opened with an introductory lecture by Prof. J. Risien Russell. The session of the London (Royal Free Hospital) School of Medicine for Women will be opened with an introductory lecture by Dr. F. W. Andrews. The winter session at Charing Cross Hospital will open on Wednesday, October 2, when an introductory address will be delivered by Prof. J. W. Taylor. At the inauguration of the sixtieth session of the School of Pharmacy, the Hanbury gold medal will be presented, and the inaugural address will be delivered by Dr. Arthur P. Luff. At the Royal Veterinary College the sessional course of instruction will be opened with an introductory address delivered by Dr. E. M. Crookshank. The winter session at Yorkshire College, Leeds, will open on October 1, when an introductory address will be delivered by Sir W. S. Church. At University College, Sheffield, the session will be opened with an introductory address by Sir Thomas Barlow.

SEVERAL prospectuses and calendars of technical institutions, showing the courses of work for the session just commencing, have been received. The London Polytechnics give prominence to the announcement that are recognised as qualified institutions from which students who have matriculated in the University of London may be presented for the new engineering degrees of the University. Courses of work suitable for such students have been arranged, and they should be the means of extending the knowledge of the science of engineering. In the prospectus of the Battersea Polytechnic, trade students are rightly warned against only attending classes connected with their occupations. It is pointed out that the principles of science must be studied, as well as technical subjects, if a thoroughly sound knowledge is desired. Without a working acquaintance with mathematics, mensuration and geometry it is almost impossible to make any real and useful advance in science and technology. This ought to be clearly understood, and it is worth while to consider whether students should not be compelled to give evidence of such knowledge before being permitted to join technological classes, where their presence is often a hindrance to progress. The calendar of the Northampton Institute, Clerkenwell, also contains much good advice as to the choice of studies, and the objects to be borne in mind. Among the noteworthy characteristics of the work of this Institute are the electrochemical laboratory, which has been equipped in a very complete manner, the attention given to horological engineering, and the department of optical and scientific instruments. But while there is evidence of progress in the work of our polytechnics and technical schools, there is still much to be done before they reach the standard of similar institutes in Germany and the United States, such, for instance, as the Rose Polytechnic Institute, Terre Haute, Indiana, the new calendar of which is before us. Each of the courses in this Institute occupies four years of three terms each, and no undergraduate student is permitted to elect any special or partial course. All students must take full work in one of the courses, and each member of the senior class must present a thesis recording an independent investigation at the close of the year. The value of this educational policy is indicated by the high positions which the alumni of the Institute occupy as professional engineers.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 20.—"On the Resistance and Electromotive Forces of the Electric Arc." By W. Duddell, Whitworth Scholar. Communicated by Prof. W. E. Ayrton, F.R.S.

The author considers that the new facts given in the paper assist in formulating a consistent explanation of the resistance and back E.M.F. of the arc. The values found for the resistance of the vapour column and for the contacts between it and the electrodes offer no serious difficulties. The greater part of the two E.M.F.'s are considered as being most probably due to thermo-electric forces, and experiments in support of this view are described, in which it was found possible to obtain a P.D. of 0·6 volt by unequally heating two *solid* carbon electrodes with a blow-pipe flame, the voltmeter indicating that the hotter carbon was positive to the cooler. By using *cored* carbons and adding potassium salts, this P.D. was increased to 1·5 *volts.* It is pointed out that the differences of temperature existing in the arc must be many times as great as those which it is possible to produce with the blow-pipe, as the cooler electrode must be red-hot, or else it does not seem to make contact with the surrounding flame.

On the Resistance of an Electrolyte.—In measuring the resistance of an electrolyte by the Kohlrausch method, it is often assumed that the errors due to polarisation are avoided if the frequency of the alternating or interrupted current used is as high as a few hundred periods per second. Experiments made to test this point lead to the conclusion that unless other methods are adopted to eliminate the effects of polarisation, *it must not be assumed that the use of alternating currents of ordinary frequencies of a few hundred periods per second eliminates the possibility of errors due to polarisation.*

PARIS.

Academy of Sciences, September 2.—M. Bouquet de la Grye in the chair.—On the application of the equations of Lagrange to electrodynamic and electromagnetic phenomena, by M. E. Sarrau. The application of the method of Lagrange to electrical phenomena leads to results which are naturally in accord with the principle of energy, since this principle is only one form of the theorem of kinetic energy, and this is a consequence of the general equations. But for this agreement to exist it appears to be necessary to admit that the internal energy of a system of currents and magnets is purely kinetic, no part of it being potential.—On the quadratic transformation of Abelian functions, by M. Georges Humbert.—Observations of the Encke comet made at the Observatory of Algiers, by MM. Rambaud and Sy. Observations of the magnitude, apparent positions of comparison stars, and apparent positions of the comet taken between the 9th and 18th of August.—On the continuous deformation of surfaces, by M. G. Tzitzéica.—Outline of a general theory of mechanisms, by M. G. Koenigs.—On the equilibrium of elastic bodies, by M. R. Liouville.—Evaluation of the resistance of steel to traction deduced from the resistance to shearing, by M. Ch. Fremont. The curve for resistance to shearing per square millimetre plotted as ordinates against the resistance to extension as abscissæ is a straight line.—On the first stages of development of some Polycystidea, by MM. L. Leger and O. Duboscq. Observations on three groups of Polycystidea, *Actinocephalides, Dactylophorides,* and *Clepsidrinides,* show that the typical evolution allows no intracellular stage. They differ in this respect from the intestinal Monocystidia, as has been shown by Caullery and Mesnil.—On scissiparity in the Hydroides, by M. Armand Billard.—On the appearance of the white rot (*Charrinia Diplodiella*) in Algeria, by MM. J. D. Catta and A. Maige.—On a case of sexual determinism produced by mixed grafting, by M. A. Jurie.

WIRELESS TELEGRAPHY.

Drahtlose Telegraphie durch Wasser und Luft. Based on Lectures delivered in the Winter of 1900 by Prof. Dr. Ferdinand Braun, Director of the Physical Institute of the University of Strassburg. Pp. 68. (Leipzig: Veit and Co., 1901.) Price M. 2.

THE rapid development of wireless telegraphy which has taken place in the last few years has called forth many articles in the scientific and technical papers, but as yet but few single treatises or text-books. Prof. Braun is known as an experimenter in this branch of electrical science, and the pamphlet under notice treats of the subject from a more or less popular point of view and also gives a short sketch of some of Prof. Braun's own experiments. The first chapter is an interesting historical *résumé* of the endeavours to signal over a distance without the use of intervening wires. It is interesting to observe that the discovery that the earth could serve as a return conductor for the ordinary telegraph first led up to the thought that the other wire could also be replaced by the earth or air or other medium. In one point we think Prof. Braun's remarks are hardly in agreement with the latest of our ideas—we mean in his description of the Becquerel and radium rays as being of the nature of light and electric waves. This is hardly in accordance with the corpuscle theory, which approaches, as near as it is possible at present, to an explanation of these phenomena. The chapter after this historical introduction deals with the author's own experiments on hydrotelegraphy. The guiding idea of the work was to use the property of an alternating current, with sufficiently high frequency, to flow only on the surface of a conductor. If, now, such a current be led in and out at two points of a sheet of water, the current, instead of penetrating deep down, will tend to spread itself out upon the surface of the water, and by connecting a receiving circuit at any two other points, messages can be passed between the two stations. This method of working differs in principle from that of Rathenau and Strecker, who used stationary currents. With this arrangement, if the receiver be connected to two points lying on an equipotential line, *i.e.* a line drawn at right angles to the current lines, no messages can be received. With Braun's arrangement this is different, due to the fact that the equipotential lines continually change. With experiments made at Cuxhaven, signals could be sent for a distance of three kilometres, it being proved that the effect was neither transmitted through the air nor was it an induction effect similar to Preece's experiments. All the results agree fully with the enunciated principle.

It is difficult, however, to think, in spite of the author's hopes, that this system will ever be of much practical importance in view of the development of the Marconi system.

The second chapter gives an account of Prof. Braun's experiments on wireless telegraphy proper. The results of these experiments have been published in various papers and have also received attention in this Journal. The transmitter arrangement mostly used by Braun is that of inductive excitement. Tested against the Marconi arrangement, much better results were obtained, and Prof. Braun is of opinion that this is the best of all the devised arrangements up to date. It must be remembered, however, that Marconi has considerably improved his apparatus quite recently and has now obtained results better than those given here.

The next chapter is on "tuned telegraphy"; it is pointed out that an un- or very little damped vibration is the first condition for good syntony. This principle is now universally recognised.

In his final remarks, Prof. Braun is of opinion that the hopes that have been entertained that wireless telegraphy will ever displace the ordinary wire telegraphy are an illusion, a conclusion which is now becoming general. The spheres of usefulness of wireless telegraphy are, however, even without this, very great, and in the near future will greatly develop.

As a short, clearly written contribution to the literature of the subject, the book is worth reading. C. C. G.

OUR BOOK SHELF.

Geometrical Exercises from Nixon's "Euclid Revised," with Solutions. By Alexander Larmor, M.A. Pp. vi + 170. (Oxford: Clarendon Press, 1901.)

THIS is a collection of 823 examples illustrating the various propositions of Euclid's six books, as well as many other domains of the geometry of the right line and circle, such as maxima and minima, collinearity and concurrency, centres of similitude, coaxal circles, inversion, harmonic ranges, poles and polars, and the modern geometry of the triangle. It will thus be seen that everything of importance in the subject is dealt with. Hints are given for the solution of all the more easy questions, while fully worked out solutions are given for the more advanced. The work is therefore one of very great value both for the student and for the teacher. All the classical problems and theorems in the subject are associated with the names of their discoverers—Ptolemy, Euler, Pascal, Brianchon, Simson, &c.—and each receives ample illustration and application. This is one of the many good features of the work. Mr. Larmor is quite right in maintaining that the student of geometry should be provided with a copious and varied collection of exercises, and with an opportunity for consulting the solution of a problem or theorem in which he has failed while his interest in it is still fresh. Such an opportunity is afforded by this excellent representative collection. Doubtless much assistance in this way is derivable from the work of the late Prof. Townsend; but his book is, perhaps, too elaborate and unmanageable for the average student, on whose attention many other branches of mathematics now make large demands.

Histoire du Ciel. Par Clémence Royer. Pp. 246. (Paris: Librairie C. Reinwald, 1901). Price 2 fcs. 50.

WHILE correctly stating a considerable number of facts, this little book, which forms the first volume of a "Petite Encyclopédie Scientifique du XX^e Siècle," by no means represents the state of astronomical science at the present time. The earlier chapters recount the history of astronomy to the time of Newton, but afterwards the bulk of the matter is descriptive and speculative. So little acquainted is the author with recent work, that among many strange ideas expounded we find the suggestion that the rings of Saturn are not composed of multitudes of small bodies but of coherent masses of ice. The illustrations are very poor, and the book should be avoided by those desiring a trustworthy guide to current opinions.

 Y

THE DENVER MEETING OF THE AMERICAN ASSOCIATION.

THE American Association held its fiftieth annual meeting at Denver, Colorado, during the week beginning August 24, under the presidency of Prof. Charles S. Minot, of Harvard University. This is the first time that the Association has met west of the banks of the Mississippi River, and the meeting consequently marks a somewhat important epoch in the development of science in America. The central and western States have occupied somewhat the same position towards the Atlantic seaboard as this part of the country held in relation to Europe until about twenty-five years ago. Until the development of the eastern universities, the scientific men of the United States were largely trained abroad and looked chiefly to Great Britain and the Continent for their scientific models. Up to the present time the central and western States—engaged in subduing Nature on a scale hitherto unattempted—have depended on the Atlantic States for their education, their science and their literature. The development of the universities in the central and western States during the past ten years has, however, been remarkable. Of the forty universities in the world having more than 2000 students, seven—Michigan, Chicago, North-Western, Wisconsin, Minnesota, Illinois and California—are situated in this region; and these institutions are not mere schools, but universities and centres for the advancement of science, rivalling Leipzig or Cambridge in their standards and in their productiveness. The time has obviously come when men of science in the west can meet on equal terms their colleagues in the east, and this event was signalised by the meeting of the Association at Denver, midway between the Atlantic and Pacific coasts. The meeting, though not so largely attended as is usual further to the east—the members from either the Atlantic or Pacific coasts had 2000 miles to travel—was successful both on its social and scientific sides. Hospitality is the virtue of a new country, and the people of Denver were prepared to entertain the Association by social functions and excursions in a way that is not usual in the United States.

Before the ten sections into which the Association is divided some two hundred and twenty papers were presented, and while perhaps none of them was of such importance as to deserve special notice, they represented on the whole a high level of scientific work. The address of the retiring president, Prof. R. S. Woodward, of Columbia University, appears in the present issue of NATURE. Public addresses on topics suited to the place of meeting were made by Prof. C. R. Van Hise, who discussed the nature of ore deposits, and by Mr. Gifford Pinchot, chief of the Bureau of Forestry, who considered questions of irrigation and forestration.

Owing to a change in procedure by which the chairmen of sections give their addresses when retiring from office, there were this year only five such addresses. Before the section of chemistry, Prof. J. H. Long, of North-Western University, took as the subject of his address the development of the teaching of chemistry in the United States; before the section of mechanical science and engineering, Mr. John A. Brashear, acting Chancellor of the Western University of Pennsylvania, described the plans, drawn up at Mr. Carnegie's request, for a great technical college at Pittsburg which would call for an endowment of from 10,000,000 to 20,000,000 dollars; before the section of zoology, Prof. Charles B. Davenport, of the University of Chicago, discussed the quantitative study of variation—a subject to which he has devoted special attention, being associated with Profs. Pearson and Weldon in the newly established journal *Biometrika*; before the section of anthropology, Mr. Amos W. Butler, of the Indiana State Board of Charities, described the methods used under his direction for the care of the feeble minded in the State of Indiana, with scientific deductions on heredity and the like; before the section of social and economic science, Prof. C. M. Woodward, of Washington University, St. Louis, and a leader in the introduction of manual training into the schools of the United States, discussed what he called "The change of front in education." A new section of the Association, devoted to physiology and experimental medicine, was organised and will hold its first meeting for the reading of papers next year.

The business transacted at the meeting was of unusual importance. The first report was made in regard to the plan of sending the weekly journal, *Science*, free of charge to all members of the Association. It is apparently working well, for this and the efficiency of the present permanent secretary, Dr. L. O. Howard, has resulted in an addition of about 1500 permanent new members, chiefly scientific men, in the course of the year. The American Association is becoming a centre for national scientific societies, and hereafter the societies devoted to the special sciences will be represented on the council of the Association. Efforts have recently been made to secure for America a convocation week for the meetings of scientific and learned societies, and the leading universities have agreed to set aside for this purpose the week in which January 1 falls. The American Association will hold a meeting in mid-winter at Washington at the beginning of the year 1903, when there will be a congress of at least twenty scientific societies. The next meeting of the Association will, however, be at Pittsburg at the beginning of next July. It will be presided over by the eminent astronomer, Dr. Asaph Hall.

ADDRESS BY PROF. R. S. WOODWARD, PRESIDENT OF THE ASSOCIATION.

The Progress of Science.

A CONSTITUTIONAL provision of our Association stipulates that "It shall be the duty of the President to give an address at a General Session of the Association at the meeting following that over which he presided." Happily for those of us who must in turn fulfil this duty, the scientific foresight of our predecessors set no metes and bounds with respect to the subject-matter or the mode of treatment of the theme that might be chosen for such an address. So far, therefore, as constitutional requirements are concerned, a retiring president finds himself clothed for the time being with a degree of liberty which might be regarded as dangerous were it not for an unwritten rule that one may not hope to enjoy such liberty more than once. But time and place, nevertheless, as well as the painful personal limitations of any specialist, impose some rather formidable restrictions. One may not tax lightly, even, in a summer evening, the patience of his audience for more than an academic hour, the length of which in most cases is less than sixty minutes. One must confine himself to generalities, which, though scientifically hazardous, serve as a basis for semi-popular thought; and one must exclude technical details, which, though scientifically essential, tend only to obscure semi-popular presentation. Courtesy, also, to those who are at once our hosts and our guests requires that, so far as possible, one should substitute the vernacular for the "jargon of science," and draw his figures of speech chiefly from the broad domain of every-day life rather than from the special, though rapidly widening, fields of scientific activity.

Between this nominally unlimited freedom on the one hand, and these actually narrow restrictions on the other, I have chosen to invite your attention for the hour to a summary view of the salient features of scientific progress, with special reference to its effects on the masses, rather than on the individuals, of mankind. We all know, at least in a general way, what such progress is. We are assured almost daily by the public Press and by popular consent that the present is not only an age of scientific progress but that it is preeminently the age of scientific progress. And with respect to the future of scientific achievement, the consensus of expert opinion is cheerfully hopeful and the consensus of public opinion is extremely optimistic. Indeed, to borrow the language sometimes used by the rulers of nations, it may be said that the realm of science is now at peace with all foreign parts of the world and in a state of the happiest domestic prosperity.

But times have not been always thus pleasant and promising for science. As we look backward over the history of scientific progress it is seen that our realm has been taxed often to the utmost in defence of its autonomy, and that the present state of domestic felicity, bordering on tranquillity, has been preceded often by states of domestic discord bordering on dissolution. And, as we look forward into the new century before us, we may well inquire whether science has vanquished its foreign enemies and settled its domestic disputes for good and all, or whether future conquests can be made only by a similarly wasteful outlay of energy to that which has accompanied the advances of the past. Especially may we fitly inquire on an occasion like the present what are the types of mind and the methods of procedure which make for the progress, and what are the types of mind and the methods of procedure which make for the regress, of science. And I venture to think that we may inquire also with profit, in some prominent instances, under what circumstances in the past science has waxed or waned, as the case may be, in its slow rise from the myths and mysticism of earlier eras to the law and order of the present day. For it is a maxim of common parlance, too well justified, alas! by experience, that history repeats itself; or, to state the fact less gently, that the blunders and errors of one age are repeated with little variation in the succeeding age. This maxim is strikingly illustrated by the history of science, and it has been especially deeply impressed upon us—burnt in, one might say—by the scientific events of our own times. Have we not learned, however, some lasting lessons in the hard school of experience, and may we not transmit to our successors along with the established facts and principles of science the almost equally well established ways and means for the advancement of science? Will it be possible for society to repeat in the twentieth century the appalling intellectual blunders of the nineteenth century, or have we entered on a new era in which, whatever other obstacles are pending, we may expect man to stand notably less in his own light as regards science than ever before? To a consideration of these and allied questions I beg your indulgence, even though I may pass over ground well known to most of you, and encroach, perhaps, here and there, on prominences in fields controversial; for it is only by discussion and rediscussion of such questions that we come at last, even among ourselves in scientific societies, to the unity of opinion and the unity of purpose which lead from ideas to their fruitful applications.

From the earliest historic times certainly, if not from the dawn of primitive humanity, down to the present day, the problem of the universe has been the most attractive and the most illusive subject of the attention of thinking men. All systems of philosophy, religion and science are alike in having the solution of this problem for their ultimate object. Many such systems and sub-systems have arisen, flourished and vanished, only to be succeeded by others in the seemingly Sisyphean task. Gradually, however, in the lapse of ages there have accumulated some elements of knowledge which give inklings of partial solutions; though it would appear that the best current opinion of philosophy, religion and science would again agree in the conclusion that we are yet immeasurably distant from a complete solution. Almost equally attractive and interesting, and far more instructive, as it appears to me, in our own time is the contemplation of the ways in which man has attacked this perennial riddle. It is, indeed, coming to be more and more important for science to know how primitive, barbarous, and civilised man has visualised the conditions of, and reached his conclusions with respect to, this problem of the centuries; for it is only by means of a lively knowledge of the baseless hypotheses and the fruitless methods of our predecessors that we can hope to prevent history from repeating itself unfavourably.

Looking back over the interval of two to three thousand years that connects us by more or less authentic records with our distinguished ancestors, we are at once struck by the admirable confidence they had acquired in their ability to solve this grand problem. Not less admirable, also, for their ingenuity and for the earnestness with which they were advanced, are the hypotheses and the arguments by which men satisfied themselves of the security of their tenets and theories. Roughly speaking, it would appear that the science of the universe received its initial impulse from earliest man in the hypothesis that the world is composed of two parts, the first and most important part being, in fact, if not always so held ostensibly, himself, and the other part being the aggregate of whatever else was left over. Though dimly perceived and of little account in its effects, this is, apparently, the working hypothesis of many men in the civilised society of to-day. But the magnitude of the latter part and its inexorable relations to man seem to have led him speedily to the adoption of a second hypothesis, namely, that the latter part, or world external to himself, is also the abode of sentient beings, some of a lower and some of a higher order than man, their *rôle* tending on the whole to make his sojourn on this planet tolerable and his exit from it creditable, while yet wielding at times a more or less despotic influence over him.

How the details of these hypotheses have been worked out is a matter of something like history for a few nationalities, and is a matter absorbing the attention of anthropologists, archæologists, and ethnologists as it concerns races in general. Without going far afield in these profoundly interesting and instructive details, it may suffice for the present purposes to cite two facts which seem to furnish the key to a substantially correct interpretation of subsequent developments.

The first of these is that the early dualistic and antithetical visualisation of the problem in question has persisted with wonderful tenacity down to the present day. The accessible and familiar was set over against the inaccessible and unfamiliar; or, what we now call the natural, though intimately related to, was more or less opposed to the supernatural, the latter being, in fact, under the uncertain sway of, and the former subject to the arbitrary jurisdiction of, good and evil spirits.

The second fact is that man thus early devised for the investigation of this problem three distinct methods, which have likewise persisted with equal tenacity, though with varying fortunes, down to the present day. The first of these is what is known as the *a priori* method. It reasons from subjective postulates to objective results. It requires, in its purity, neither observation nor experiment on the external world. It often goes so far, indeed, as to adopt conclusions and leave the assignment of the reasons for them to a subsequent study. The second is known as the historico-critical method. It depends, in its purity, on tradition, history, direct human testimony and verbal congruity. It does not require an appeal to Nature except as manifested in man. It limits observation and experiment to human affairs. The third is the method of science. It begins, in its elements, with observation and experiment. Its earlier applications were limited mostly to material things. In its subsequent expansion it has gained a footing in nearly every field of thought. Its prime characteristic is the insistence on objective verification of its results.

All of these methods have been used more or less by all thinking men. But for the purposes of ready classification it may be said that the first has been used chiefly by dogmatists, including especially the founders and advocates of all fixed creeds from the atheistic and pantheistic to the theistic and humanistic; the second has been used chiefly by humanists, including historians, publicists, jurists and men of letters; and the third has been used chiefly by men of science, including astronomers, mathematicians, physicists, naturalists and, more recently, the group of investigators falling under the comprehensive head of anthropologists. The first and the third methods are frequently found to be mutually antithetical, if not mutually exclusive. The second occupies middle ground. Together they are here set down in the order of their apparent early development and in the order of their popularly esteemed importance during all historic time previous to, if not including, this first year of the twentieth century.

No summary view of the progress of science, it seems to me, can be made intelligible except by a clear realisation of these two facts, which may be briefly referred to as man's conception of the universe and his means of investigating it. What, then, in the light of these facts, has been the sequel? The full answer to this question is an old and a long story, now a matter of minute and exhaustive history as regards the past twenty centuries. I have no desire to recall the dramatic events involved in the rise of science from the Alexandrian epoch to the present day. All these events are trite enough to men of science. A mere reference to them is a sufficient suggestion of the existence of a family skeleton. But, setting aside the human element as much as possible, it may not be out of place or time to state what general conclusions appear to stand out clearly in that sequel. These are our tangible heritage, and upon them we should fix our attention.

In the first place, the progress of science has been steadily opposed to, and as steadily opposed by, the adherents of man's primitive concepts of the universe. The domain of the natural has constantly widened and the domain of the supernatural has constantly narrowed. So far, at any rate, as evil spirits are concerned, they have been completely cast out from the realm of science. The arch fiend and the lesser princes of darkness are no longer useful even as an hypothesis. We have reached—if I may again use the cautious language of diplomacy—a satisfactory *modus vivendi* if we have not attained permanent peace in all our foreign relations. Enlightened man has come to see that his highest duty is to cooperate with Nature, that he may expect to get on very well if he heeds her advice, and that he may expect to fare very ill if he disregards it.

Secondly, it appears to have been demonstrated that neither the *a priori* method of the dogmatists nor the historico-critical method of the humanists is alone adequate for the attainment of definite knowledge of either the internal or the external world, or of their relations to one another. In fact, it has been shown over and over again that man cannot trust his unaided senses even in the investigation of the simplest and most obvious material phenomena. There is an ever present need of a correction for personal equation. Left to himself, the *a priori* reasoner weaves from the tangled skein of thought webs so well tied by logical knots that there is no escape for the imprisoned mind except by the rude process applied to cobwebs. And in the serenity of his repose behind the fortress of "liberal culture" the reactionary humanist will prepare apologies for errors and patch up compromises between traditional beliefs and sound learning with such consummate literary skill that even "the good demon of doubt" is almost persuaded that if knowledge did not come to an end long ago it will soon reach its limit. In short, we have learned, or ought to have learned, from ample experience, that in the search for definite, verifiable knowledge we should beware of the investigator whose equipment consists of a bundle of traditions and dogmas along with formal logic and a facile pen; for we may be sure that he will be more deeply concerned with the question of the safety than with the question of the soundness of scientific doctrines.

Thirdly, it has been demonstrated equally clearly and far more cogently that the sort of knowledge we call scientific, knowledge which has in it the characteristics of immanence and permanence, is founded on observation and experiment. The rise and growth of every science illustrate this fact. Even pure mathematics, commonly held to be the *a priori* science par excellence, and sometimes called "the science of necessary conclusions," is no exception to the rule. Those who would found mathematics on a higher plane have apparently forgotten to consider the contents of the mathematician's waste-basket. The slow and painful steps by which astronomy has grown out of astrology and chemistry out of alchemy; and the faltering, tedious, and generally hotly contested advances of geology and biology, have been made secure only by the remorseless disregard which observational and experimental evidence has shown for the foregone conclusions of the dogmatists and the literary opinions of the humanists. Thus it has been proved by the rough logic of facts and events that the rude processes of "trial and error," processes which many philosophers and some men of science still affect to despise, are the most effective means yet devised by man for the discovery of truth and for the eradication of error.

These facts are so well known to most of you, so much a matter of ingrained experience, that the categorical mention of them here may seem like a rehearsal of truisms. But it is one of the paradoxes of human development that errors which have been completely dislodged from the minds of the few may still linger persistently in the minds of the many, and that the misleading hypotheses and the dead theories of one age may be resuscitated again and again in succeeding ages. Thus, to cite one of the simplest examples, it doubtless appeared clear to the Alexandrian school that the flat, four-cornered earth of contemporary myths would speedily give way to the revelations of geometry and astronomy. How inadequate such revelations proved to be at that time is one of the most startling disclosures in all history. The "Divine School of Alexandria" passed into oblivion. The myth of a flat and four-cornered earth was crystallised into a dogma strong enough to bear the burden of men's souls by Cosmas Indicopleustes in the sixth century; it was supported with still more invincible arguments by Martin Luther in the sixteenth century; and it was revived and maintained with not less truly admirable logic, as such, by John Hampden and John Jasper in the last decades of the nineteenth century. To cite examples from contemporary history showing how difficult it is for the human mind to get above its primitive conceptions, one needs only to refer to the daily Press. During the past two months, in fact, the newspapers have related how men, women and children, many of them suffering from loathsome if not contagious diseases, have visited a veritable middle-age shrine in the city of New York, strong in the hoary superstition that kissing an alleged relic of St. Anne would remove their afflictions. During the same interval a railway circular has been distributed explaining how tourists may witness the Moki snake-dance, that weird ceremony by which the Pueblo Indian seeks to secure rain in his desert; and a similar public, and officially approved, ceremony has been observed in the heat-stricken State of Missouri.

Such epochs and episodes of regression as these must be taken into account in making up an estimate of scientific progress. They show us that the slow movement upward in the evolution of man which gives an algebraic sum of a few steps forward per century is not inconsistent with many steps backward. Or, to state the case in another way, the rate of scientific advance is to be measured not so much by the positions gained and held by individuals, as by the positions attained and realised by the masses of our race. The average position of civilised man now is probably below the mean of the positions attained by the naturalist Huxley and the statesman Gladstone, or below the mean of the positions attained by the physicist von Helmholtz and His Holiness the Pope. When measured in this manner, the rate of progress in the past twenty centuries is not altogether flattering or encouraging to us, especially in view of the possibility that some of the recently developed sciences may suffer relapses similar to those which so long eclipsed geography and astronomy.

It must be confessed, therefore, when we look backward over the events of the past two thousand years, and when we consider the scientific contents of the mind of the average denizen of this planet, that it is not wholly rational to entertain millennial anticipations of progress in the immediate future. The fact that some of the prime discoveries of science have so recently appeared to many earnest thinkers to threaten the very foundations of society is one which should not be overlooked in these confident times of prosperity. And the equally important fact that entire innocence with respect to the elements of science and dense ignorance with respect to its methods have not been hitherto incompatible with justly esteemed eminence in the divine, the statesman, the jurist, and the man of letters, is one which should be reckoned with in making up any forecast. It may be seriously doubted, indeed, whether the progress of the individual is not essentially limited by the progress of the race.

But this obverse and darker side of the picture which confronts us from the past has its reverse and brighter side; and I am constrained to believe that the present status of science and the general enlightenment of humanity justify ardent hopefulness if not sanguine optimism with respect to the future of scientific achievement. The reasons for this hopefulness are numerous; some of them arising out of the commercial and political conditions of the world, and others arising out of the conditions of science itself.

Perhaps the most important of all these reasons is found in the general enlargement of ideas which has come, and is coming, with the extension of trade and commerce to the uttermost parts of the earth. We are no longer citizens of this or that country, simply. Whether we wish it or not we are citizens of the world, with increased opportunities and with increased duties. We may not approve—few men of science would approve, I think—that sort of "expansion" which works "benevolent assimilation" of inferior races by means of a bible in one hand and a gun in the other; but nothing can help so much, it seems to me, to remove the stumbling blocks in the way of the progress of science as actual contact with the manners, the customs, the relations, and the resulting questions for thought, now thrust upon all civilised nations by the events of the day. That sort of competition which is the life of trade, that sort of rivalry which is the stimulus to national effort, and that sort of cooperation which is essential for mutual protection, all make for the cosmopolitan dissemination of scientific truth and for the appreciation of scientific investigation. I would not disparage the elevated aspirations and the noble efforts of the evangelists and the humanists who seek to raise the lower to the plane of the higher elements of our race; but it is now plain as a matter of fact, however repulsive it may seem to some of our inherited opinions, that the railway, the steamship, the telegraph, and the daily Press will do more to illumine the dark places of the earth than all the apostles of creeds and all the messengers of the gospel of "sweetness and light."

A question of profound significance growing out of the extension of commercial relations in our time is what may be called the question of international health. An outbreak of cholera in Hamburg, the prevalence of yellow fever in Havana, or an epidemic of bubonic plague in India is no longer a matter of local import, as nations with which we are well acquainted have learned recently in an expensive manner. The management of this great international question calls for the application of the most advanced scientific knowledge and for the most intricate scientific investigation. Large sums of money must be devoted to this work, and many heroic lives will be lost, doubtless, in its execution; but it is now evident, as a mere matter of international political economy, that the cost of sound sanitation will be trifling in comparison with the cost of no sanitation; while further careful study of the natural history of diseases promises practical immunity from many of them at no distant day. International associations of all kinds must aid greatly also in the promotion of progress. Many such organisations have, indeed, already undertaken scientific projects with the highest success. Comparison and criticism of methods and results not only lead rapidly and effectively to improvements and advances, but they lead also to a whole-hearted recognition of good work which puts the fraternalism of men of science on a plane far above the level of the amenities of merely diplomatic life.

When we turn to the general status of science itself, there is seen to be equal justification for hopefulness founded on an abundance of favourable conditions. The methods of science may be said to have gained a footing of respectability in almost every department of thought, where, a half century ago, or even twenty years ago, their entry was either barred out or stoutly opposed. The "Conflict between Religion and Science"—more precisely called the conflict between theology and science—which disturbed so many eminent though timid minds, including not a few men of science, a quarter of a century ago, has now been transferred almost wholly to the field of the theological contestants; and science may safely leave them to determine the issue, since it is evidently coming by means of scientific methods. The grave fears entertained a few decades ago by distinguished theologians and publicists as to the stability of the social fabric under the stress put upon it by the rising tide of scientific ideas have not been realised. And, on the other hand, the grave doubts entertained by distinguished men of science a few decades ago as to the permeability and ready response of modern society to that influx of new ideas have likewise not been realised. It is true that we sometimes read of theological tests being applied to teachers of biology, and hear, occasionally, of an earnest search for a good Methodist or a good Presbyterian mathematician; but such cases may be left for settlement out of court by means of the arbitration of our sense of humour.

It seems not unlikely, also, that there may persist, for a long time to come, a more or less guerilla "warfare of science" with our friends the dogmatists and the humanists. Some consider this conflict to be, in the nature of things, irrepressible. But I think we may hope, if we may not confidently expect, that the collisions of the future will occur more manifestly than they have in the past in accordance with the law of the conservation of energy; so that the heat evolved may reappear as potential energy in the warmth of a kindly reasonableness on both sides, rather than suffer degradation to the level of cosmic frigidity.

Great questions, also, of education, of economic, industrial and social conditions, and of legal and political relations are now demanding all the light which science can bring to bear upon them. Though tardily perceived, it is now admitted, generally, that science must not only participate in the development of these questions but that it alone can point the way to the solutions of many of them. But there is no halting ground here. Science must likewise enter and explore the domain of manners and morals; and these, though already largely modified unconsciously, must now be modified consciously to a still greater extent by the advance of science. Only within quite recent times have we come to realise an approximation to the real meaning of the trite saying that the true study of man is man. So long as the most favoured individuals of his race, accordance with the hypothesis of the first centuries, looked upon him as a fallen, if not a doomed, resident of an abandoned reservation, there could be roused little enthusiasm with respect to his present condition; all thought was concentrated on his future prospects. How incomparably different does he appear to the anthropologist and to the psychologist at the beginning of the twentieth century! In the light of evolution he is seen to be a part of, and not apart from, the rest of the universe. The transcendent interest of this later view of man lies in the fact that he can not only investigate the other parts of the universe, but that he can, by means of the same methods, investigate himself.

I would be the last to look upon science as furnishing a speedy or a complete panacea for the sins and sorrows of mankind; the destiny of our race is entangled in a cosmic process whose working is thus far only dimly outlined to us; but it is nevertheless clear that there are available to us immense opportunities for the betterment of man's estate. For example, to mention only one of the lines along which improvement is plainly practicable, what is to hinder an indefinite mitigation, if not a definite extinction, of the ravages of such dread diseases as consumption and typhoid fever? Or what, we may ask, is to hinder the application to New York, Philadelphia and Chicago of as effective health regulations as those now applied to Havana? Nothing, apparently, except vested interests and general apathy. We read, not many years ago, that a city of about one million inhabitants had, during one year, more than six thousand cases of typhoid fever. The cost to the city of a single case may be estimated as not less, on the average, than one thousand dollars, making an aggregate cost to that city, for one year, of more than six millions of dollars. Such a waste of financial resources ought to appeal to vested interests and general apathy even if they cannot be moved by any higher motives. Thanks to the penetration of the enlightenment of our times, distinct advances have already been made in the line of effective domestic and public sanitation; but the good work accomplished is infinitesimal in comparison with that which can be, and ought to be, done. It is along this, and along allied lines of social and industrial economy, that we should look, I think, for the alleviation of the miseries of mankind. No amount of contemplation of the beatitudes, human or divine, will prevent men from drinking contaminated water or milk; and no fear of future punishments, which may be in the meantime atoned for, will much deter men from wasting their substance in riotous living. The moral certainty of speedy and inexorable earthly annihilation is alone adequate to bring man into conformity with the cosmic rules and regulations of the drama of life.

And, finally, we must reckon amongst the most important of the conditions favourable to the progress of science the unexampled activity in our times of the scientific spirit as manifested in the work of all kinds of organisations from the semi-religious Chautauquan assemblies up to those technical societies whose programmes are Greek to all the world beside. Literature, linguistics, history, economics, law and theology are now permeated by the scientific spirit, if not animated by the scientific method. Curiously enough, also, the terminology, the figures of speech and the points of view of science are now quite common in realms of thought hitherto held somewhat scornfully above the plane of materialistic phenomena. Tyndall's Belfast address, which, twenty-seven years ago, was generally anathematised, is now quoted with approval by some of the successors of those who bitterly denounced him and all his kind. Thus the mere lapse of time is working great changes and smoothing out grave differences of opinion in favour of the progress of science in all the neighbouring provinces with which we have been able hitherto to maintain only rather strained diplomatic relations.

Still more immediately important to us are the evidences of progress manifested in recent years by this Association and by its affiliated societies. Our parent organisation, though half a century old, is still young as regards the extent in time of the functions it has undertaken to perform. It has accomplished a great work; but in the vigour and enthusiasm of its youth a far greater work is easily attainable. Exactly how these functions are to be developed no man can foresee. We may learn, however, in this, as in other lines of research, by methods with which we are well acquainted, namely, by the methods of carefully planned and patiently executed observation and experiment. The field for energetic and painstaking effort is wider and more attractive than ever before. Science is now truly cosmopolitan; it can be limited by no close corporations, and no domain of scientific investigation can be advantageously fenced off, either in time or in place, from the rest. While every active worker of this or of any affiliated society is, in a sense, a specialist, there are occasions when he should unite with his colleagues for the promotion of science as a whole. The results of the specialists need to be popularised and to be disseminated among the people at large. The advance of knowledge to be effective with the masses of our race must be sustained on its merits by a popular verdict. To bring the diverse scientific activities of the American continent into harmony for common needs; to secure cooperation for common purposes; and to disseminate the results of scientific investigation among our fellow-men, are not less, but rather much more, than in the past the privilege and the duty of the American Association for the Advancement of Science.

Viewed, then, in its broader aspects, the progress of science is involved in the general progress of our race; and those who are interested in promoting the former should be equally earnest in securing the latter. However much we may be absorbed in the details of our specialities, when we stop to think of science in its entirety, we are led, in the last analysis, back to the problem of problems—the meaning of the universe. All men "gifted with the sad endowment of a contemplative mind" must recur again and again to this riddle of the centuries. We are, so to speak, whatever our prepossessions, all sailing in the same boat on an unknown sea for a destination at best not fully determined. Some there are who have, or think they have, the Pole Star always in sight. Others, though less confident of their bearings, are willing to assume nothing short of second place in the conduct of the ship. Others, still less confident of their bearings, are disposed to depend chiefly on their knowledge of the compass and on their skill in dead reckoning. We of the latter class may not impugn the motives or doubt the sincerity of the first two classes. We would find it difficult, probably, to dispense with their company in so long a journey after becoming so well acquainted with them; for among them we may each recall not a few of those rarer individuals of the genus homo called angels on earth. But it must be said in all truth, to resume the figure, that they have neither improved much the means of transportation nor perfected much the art of navigation. They have been sufficiently occupied, perhaps, in allaying the fears of the timid and in restraining the follies of the mutinous. Other types of mind and other modes of thought than theirs have been essential to work out the improvements which separate the earlier from the later nautical equipments of men; such improvements, for example, as mark the distinction between the dug-out of our lately acknowledged relatives, the Moros and the Tagalogs, from the Atlantic-liner of to-day. At any rate, we are confronted by the fact that man's conceptions of the universe have undergone slow but certain enlargement. His early anthropocentric and anthropomorphic views have been replaced, in so far as he has attained measurable advancement, by views that will bear tests of astronomy and anthropology. He has learned, slowly and painfully, after repeated failures and many steps backward, to distinguish, in some regions of thought, the real and the permanent from the fanciful and fleeting phenomena of which he forms a part. His pursuit of knowledge, in so far as it has led him to certainty, has been chiefly a discipline of disillusionment. He has arrived at the truth not so much by the genius of direct discovery as by the laborious process of the elimination of error. Hence he who has learned wisdom from experience must look out on the problem of the universe at the beginning of the twentieth century with far less confidence in his ability to speedily solve it, and with far less exaggerated notions of his own importance in the grand aggregate of Nature, than man entertained at the beginning of our era. But no devotee of science finds humiliation in this departure from the primitive concepts of humanity. On the contrary, he has learned that this apparent humiliation is the real source of enlightenment and encouragement; for notwithstanding the relative minuteness of the speck of cosmic dust on which we reside, and notwithstanding the relative incompetency of the mind to discover our exact relations to the rest of the universe, it has yet been possible to measure that minuteness and to determine that incompetency.

These, in brief, are the elements of positive knowledge at which we have arrived through the long course of unconscious, or only half-conscious, experience of mankind. All lines of investigation converge towards or diverge from these elements. It is along such lines that progress has been attained in the past, and it is along the same lines that we may expect progress to proceed in the future.

THE GLASGOW MEETING OF THE BRITISH ASSOCIATION.

THE seventy-first annual meeting of the British Association came to an end yesterday. For the purposes of the meeting the entire accommodation of the College Buildings was placed at the disposal of the Association by the University authorities, while for the opening meeting the St. Andrew's Hall was granted by the Corporation. Between 2000 and 3000 persons attended at the St. Andrew's Hall to hear the opening address of the president, Prof. A. W. Rücker, F.R.S. The retiring president, Sir William Turner, F.R.S., took the chair and introduced his successor, who afterwards delivered the presidential address, which was printed in last week's NATURE; and on Thursday morning the work of the sections commenced. Reports of the proceedings of the sections will appear in these columns as in previous years.

Melancholy interest was given to the meeting by the expressions of sympathy sent to the United States by the Association in connection with the assassination of the late President M'Kinley. At the first meeting of the General Committee, it was decided, upon the proposition of Sir Michael Foster, seconded by Sir John Evans, that the following telegram be sent on behalf of the Association:—"That the British Association for the Advancement of Science, assembled at Glasgow, desires to make known to President M'Kinley its feeling of horror at the attempt upon his life, its sympathy with him in his suffering, and its earnest hope for his speedy and complete restoration to health." A reply expressing thanks for the sympathy was received from the late President's secretary on Thursday evening.

The news of the death of President M'Kinley became known on Saturday morning, when only two sections of the Association were sitting. At the close of the meeting of one of these sections—Educational Science—Sir John Gorst, the president, referred in touching terms to the profound grief which British people share with those of the United States at the terrible event that had occurred. The members present stood while expression was being given to their feelings by the president, and the following resolution, moved by him and seconded by Sir Philip Magnus, was adopted in solemn silence:—

"That this section of the British Association has heard with profound grief of the death of President M'Kinley, and records its deep sympathy with the family of the late President and the people of the United States of America in their domestic and national bereavement."

Many distinguished members of the Association were present at the opening by Lord Lister, on September 12, of the new Anatomical Department of Glasgow University, comprising an extensive laboratory, museum, &c. The building has been presented to the University by the trustees of the late Mr. J. B. Thomson, and Lord Lister, in opening this important addition to the resources of the University, remarked that it comprised "as fine a laboratory as existed in the world, and at the same time a capacious, commodious, and beautiful anatomical museum adjoining it." Prof. Cleland has presented to the University his large collection of anatomical specimens, and this, with the specimens collected by his predecessors and placed in the museum, makes the anatomical department a place where work can be carried on under excellent conditions.

In considering the general success of the meeting, it must be borne in mind that many citizens of Glasgow had their scientific interests almost exhausted before the meeting began, by the International Engineering Congress which immediately preceded it. It is well understood locally that the many congresses and celebrations which have been held in Glasgow since last June supply the reason for the comparatively small attendance at this year's meeting of the Association. The first Glasgow meeting in 1855 was attended by 2133 members and associates, and the total number present at the second meeting in 1876 was 2774. This year, however, the attendance has scarcely reached 1900. But the many claims which the City and Universities authorities have had upon their hospitality did not diminish the liberality of the welcome extended to the Association. Throughout the meeting the social as well as the scientific pleasures of the members have been attended to in the most generous manner. For instance, the reception given by the Corporation in the magnificent City Chambers will be remembered by everyone who attended it as one of the most brilliant yet given in honour of the Association.

Next year's meeting will be held at Belfast, and will begin on September 10, 1902. Prof. James Dewar, F.R.S., will be the president. The vice-presidents for the meeting will be the Marquis of Dufferin and Ava, the Lord-Lieutenant of County Down, the Marquis of Londonderry, Sir Francis Macnaughten, the Lord-Lieutenant of County Antrim, the Right Honourable the Earl of Shaftesbury, the Right Honourable the Earl of Rosse, the Lord Mayor of Belfast, the president of Queen's College, Belfast; Rev. Dr. Salmon, the president of Trinity College, Belfast; Sir William Quartus Ewart, the Right Honourable Thomas Sinclair, and Prof. E. Ray Lankester, F.R.S.

The meeting in 1903 will be held at Southport.

The following is a synopsis of grants of money appropriated to scientific purposes by the General Committee at the meeting on Monday:—

Mathematics and Physics.	
*Rayleigh, Lord—Electrical Standards	£40
*Judd, Prof. J. W.—Seismological Observations	35
Shaw, Mr. W. N.—Investigation of the Upper Atmosphere by means of Kites...	75
Preece, Sir W.—Magnetic Observations at Falmouth ...	80
Chemistry.	
*Hartley, Prof. W. N.—Relation between Absorption Spectra and Constitution of Organic Substances ...	20
*Roscoe, Sir H. E.—Wave-length Tables	5
Roberts-Austen, Sir Wm. C.—Properties of Metals and Alloys affected by dissolved Gases	40
Geology.	
*Marr, Mr. J. E.—Erratic Blocks (£6 in hand)	—
*Geikie, Prof. J.—Photographs of Geological Interest ...	5
*Marr, Mr. J. E.—Life-zones in British Carboniferous Rocks	10
*Watts, Prof. W. W.—Underground Water of North-West Yorkshire (balance in hand)	—
*Scharff, Dr.—Exploration of Irish Caves	45
*Woodward, Dr. H.—Type Specimens (balance in hand)	—
Zoology.	
*Herdman, Prof. W. A.—Table at the Zoological Station, Naples	100

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. PERCY F. FRANKLAND, PH.D., M.SC., F.R.S., PRESIDENT OF THE SECTION.

The Position of British Chemistry at the Dawn of the Twentieth Century.

Two circumstances unite in rendering this year especially appropriate for the survey and valuation of all departments of British life and organisation—the dawn of a new century, the close of the Victorian era. It is a moment when not only the nation as a whole, but every group of persons drawn together by whatever bond, and indeed each individual for himself, must involuntarily ask the question, Are we progressing or receding, or are we standing still? Upon us, then, who are bound together by the common interest which we have in that science to which this Section is devoted there forces itself the question, What is the position of British Chemistry at the present moment, how does this present bear comparison with the past, and what are the prospects for the future?

To bring before you some considerations with respect to the answer which should be given to this question, or rather series of questions, will be my endeavour in responding to the honour which has been conferred on me of inaugurating the work of our Section at this meeting of the Association.

It is with no light heart that I undertake this task, for there are present here to-day those whose much longer experience and far more intimate connection with the progress of our science render it presumption on my part to address them on this subject at all.

It is well known that the history of British Chemistry, as, indeed, that of British science in general, is a very remarkable one: it is almost entirely made up of achievements which are the result of private initiative; and the persons who have taken part in the making of this history have, with some notable exceptions, not been servants of the State, and have thus differed from the makers of scientific history in almost every other country in the world. Thus the opportunities for the investigations which are recorded in the *Transactions* of our Chemical Society have, for the most part, not been provided out of the public purse, but by private individuals or by institutions which have been created by private benefaction.

This unique condition of things is well illustrated by taking up a volume of the Chemical Society's *Journal* and glancing at the table of contents.

Thus in the volume for 1881, taken at random, we find that, out of the seventy-five original communications which it contains, only thirteen emanate from Government laboratories, whilst what will surely not a little surprise the scientific historian of some centuries hence is the circumstance that there are only four communications from the so-called "ancient seats of learning" of the United Kingdom, no fewer than three of which are by one and the same investigator. Again, most noteworthy is the fact that as many as five contributions are from distinguished amateurs. We have been told, on what many persons regard as high authority, that England is suffering from amateurism in all departments of life; and however true this may be as a general proposition, the amateurs of British science, like Gladstone, Schunck and Perkin amongst living chemists, are assuredly some of the most valued possessions of this country.

On looking back a quarter of a century into the past it is at once apparent how greatly during that short period of time—less than a generation of men—have the opportunities for higher chemical training been extended and multiplied in our midst. I think I shall not be far wrong in saying that until twenty-five years ago practically the only public laboratories in which the higher study of chemistry could be pursued were those of the Royal College of Chemistry, the Royal Institution, of University and King's Colleges, London, the University laboratories of England, Scotland and Ireland, as well as those of the Queen's Colleges and of the Royal College of Science in the sister island; to which must be added the laboratories of two institutions of a somewhat different type, viz. Owens College, Manchester, and Anderson's College, in this great city of the north. It is the rapid multiplication of institutions of the Owens College type that constitutes probably the most important feature in the higher intellectual development of the population of this country during the past quarter of a century; indeed, it may very possibly be found in the future that this constitutes the most striking landmark in the history of British intellectual progress during recent times. A glance at the following table will show the remarkably rapid growth of these institutions during the last quarter of the nineteenth century:—

Opening of University Colleges.

University College, London		1828
King's College, London		1831
Owens College, Manchester		1851
Durham College of Science, Newcastle		1871
University College, Aberystwyth		1872
Yorkshire College, Leeds		1875
University College, Bristol		1876
University College, Nottingham		1877
Firth College, Sheffield		1879
Mason College, Birmingham		1880
University College, Liverpool		1882
University College, Dundee		1882
University College, Cardiff		1883
University College, Bangor		1884
Finsbury Technical College	City Guilds	1883
Central Institution	City Guilds	1885

Thus the opening of the greater number of these institutions falls within the decade 1875–1884.

The benefits arising from the creation of these numerous institutions have not, however, been by any means limited to those persons who have actually taken advantage of their instruction, for their existence has stimulated the establishment of many other institutions, some of which, like the two colleges founded and maintained out of the resources of the City and Guilds of London, although more limited in their scope, afford equal or even greater opportunities for higher scientific training in the particular branches which are represented.

The foundation of these University Colleges and of other institutions for higher education by private initiative, and without a particle of assistance from the public exchequer, is quite in keeping with the history of a country in which it is recognised that the Government does not lead, but only follows where it is drawn or propelled.

It would certainly be anticipated that such a large addition to the machinery for higher scientific training as is represented by the creation of these numerous local colleges during the past twenty-five years would have had a marked influence on the output of scientific discovery in this country. We will endeavour to ascertain whether such a result is discernible in the case of chemical science. Turning to the *Transactions* of the Chemical Society, I have compiled the following table in the hope of obtaining some information on this point:—

Original Communications in the Transactions of the Chemical Society.

1849	29	1862	81	1875	49	1888	75
1850	33	1863	51	1876	54	1889	71
1851	33	1864	54	1877	58	1890	71
1852	28	1865	49	1878	61	1891	95
1853	22	1866	47	1879	84	1892	90
1854	23	1867	49	1880	75	1893	104
1855	30	1868	47	1881	75	1894	83
1856	14	1869	37	1882	65	1895	116
1857	14	1870	38	1883	63	1896	117
1858	30	1871	28	1884	57	1897	114
1859	21	1872	32	1885	85	1898	102
1860	25	1873	46	1886	85	1899	120
1861	32	1874	49	1887	88	1900	127

The activity displayed in chemical research, as measured by the number of original communications to the Chemical Society, is, however, best followed by a consideration of the aggregate number of papers contributed during the three following decades:—

Decade	Total Number of Papers in *Transactions* of Chemical Society
1855–1864	352
1865–1874	422
1875–1884	641
1885–1894	847

From these figures it is manifest, even without the application of any of those mathematical processes in which modern chemists are becoming so expert, that the most remarkable increase in the number of original investigations is indeed coincident with that decade, 1875–1884, in which the great majority of the institutions to which I have referred began to throw their prismatic rays of knowledge on many thousands who until then were sitting in shadow or even in darkness.

That these new institutions should have so immediately borne fruit in the manner I have indicated cannot fail to be surprising to those who have been associated with the early years of almost any of these colleges, for when a faithful record of the experiences of their first professors is written the extraordinary obstacles which these pioneers had to encounter, and which in so many cases they successfully overcame, should afford material for a most remarkable, instructive, and even amusing volume. The worthy founders and their executors or trustees appear in general to have supposed that it was only necessary to provide a spacious building, and then appoint a staff of professors who were to do the rest, whilst the necessity of funds for annual upkeep, for libraries, and for assistants was almost overlooked.

It has indeed been learnt by bitter experience that the cost of efficiently maintaining institutions of this most ambitious character is enormously greater than was supposed in this country twenty-five years ago, and that founding a college, far from resembling the inauguration of a remunerative business, is very like entrance into the bond of matrimony, with its attendant annually increasing demand upon the pecuniary resources of the paterfamilias.

It would not indeed be surprising if some of these modern colleges had been long debarred from contributing directly to the progress of scientific investigation in this country, for this was often assuredly considered amongst the least of the many arduous duties imposed upon their first professors. Ascertained capacity to enrich science was in some cases almost a presumptive disqualification for their chairs, or at any rate took a back seat beside enthusiasm for evening classes and faith in the efficacy of that mysterious panacea "technical instruction." It is indeed lamentable to think of the valuable years of productive work lost to the country through so much of the energy of these early professors having been sacrificed to these veritable fetishes of our would-be educational reformers.

Notwithstanding the unfavourable conditions under which most of these university colleges had in the first instance to carry on work, it was not long before they showed that they were to become, even during the tenure of office of their first professors, important centres for the prosecution of research—at least as far as chemical science was concerned. Owens College had indeed already led the way in this matter before the period with which I am more especially concerned to-day, for there the first professor of chemistry had pursued his memorable investigations on the organo-metallic compounds, and had, within the first five years after the foundation of the College, enunciated that generalisation which was subsequently extended into the *law of valency*; whilst under his successors, Sir Henry Roscoe, Schorlemmer, Harold Dixon, and Perkin, jun., the Owens College has become perhaps the largest and best equipped school of scientific chemistry in the British Islands.

From the Yorkshire College, Leeds, opened in 1875, there proceeded immediately in rapid succession that whole series of careful investigations relating more especially to specific volume and other physical constants which we associate with its first chemical professor, Thorpe, and his coadjutors.

In the west of England, where the University College of Bristol was opened in 1876, the chair of chemistry was first occupied by the man who has so recently once more proved to the world that there are discoveries made in these islands which for striking originality and independence are unsurpassed and hardly equalled elsewhere. It was during his tenure of the chair at Bristol that Ramsay, assisted by his able fellow-worker and successor Sidney Young, carried out those important and most laborious investigations on vapour pressure and the thermal properties of liquids which not only displayed his extraordinary fertility and resource as an experimenter, but also revealed that exceptional freshness of mind which has enabled him to discern new methods of attacking problems that have already engaged the attention of many able men before him.

Turning from the west of England to the Midlands, where, in 1880, there was founded, through the private munificence of the late Sir Josiah Mason, a college bearing his name, which, before even attaining its majority, was transformed at the psychological moment, as by the wand of the magician, into the University of Birmingham. The first professor of chemistry at the Mason College, my distinguished predecessor, Tilden, soon made opportunity there to continue those early researches on the terpenes with which his name will always be associated. We find him also further elaborating the important uses as a reagent of nitrosyl chloride, which he had a number of years previously shown how to prepare in a state of purity, and which has played a somewhat similar part in the exploration of the terpene hydrocarbons that phenylhydrazine has done in the elucidation of the sugar-group. In addition to these investigations we find Tilden at Birmingham also turning his attention to some of the phenomena attending the solution of salts. The younger men attached to the Mason College also found there the opportunity of enriching chemical science with the results of notable investigations; for do we not all remember Thomas Turner's valuable contributions to our knowledge of the influence of chemical composition on the physical and mechanical properties of cast iron? Whilst early amongst those detailed investigations on the phenomena of solution, which in recent years have had such far-reaching effects on the development of our science, must be mentioned Dr. Nicol's experiments on the volume changes attending the mixture of salt solutions, and on the molecular volume, the boiling point, and expansion of such solutions.

In the bleak north-east of our island, at Dundee, where a college was founded in 1882 with an extremely handsome endowment by members of the Baxter family, the first professor of chemistry, Carnelley, fired by that restless and almost perfervid energy which doubtless hastened his untimely end, soon found opportunity to interrogate Nature in various directions, notwithstanding the arduous teaching duties which his insatiable love of work had imposed upon himself. Thus, already in 1884, we find him, in his quest for material which should throw light on the periodic relationship of the elements, continuing his laborious work on melting points and publishing those two ponderous quarto volumes in which every known melting point was recorded, and forming truly one of the most remarkable compilations ever attempted in our science. Of these volumes he might indeed have said, "Exegi monumentum ære perennius," for they will assuredly prove a record of the boundless energy which characterised the man, more imperishable even than the memorial tablet erected by his admiring students and friends in the entrance hall of the Dundee laboratory, which he built and loved so well.

Yet another chemist, whose untimely death we have had to lament during the past twenty years, laboured with marked zeal in one of these new colleges, for it was at Aberystwyth that Humpidge, regardless of his delicate health and in spite of the altogether unreasonable burden of teaching duties imposed upon him by the terms of his appointment, contributed to our knowledge of the atomic weight of beryllium, and participated in establishing the position occupied by that metal in the natural classification of the elements.

Time does not permit me to further dilate upon the great activity displayed by many of the first occupants of the chairs of chemistry in these provincial University Colleges. It is also unnecessary for me to do more than remind you of the work accomplished by the two Colleges of the City and Guilds of London, the chemical laboratories of which have from their very inception been under the stimulating influences of Dr. Armstrong and Prof. Meldola, foci of research from which a number of young chemists of distinction have already emanated.

In recent years we have witnessed the genesis of another class of institution, less ambitious in their aspirations than the University Colleges, but indirectly also of much importance in their bearing upon the nurture of scientific chemistry in this country. I refer to the so-called Polytechnics which have sprung up in several parts of the metropolis, and to some other institutions of similar scope in different parts of the country. If research in the University Colleges has been the product of their professors rather than of the environment which they afford, assuredly this is even far more so in the case of these Polytechnics, which are primarily evening schools for the benefit of those who have other occupations during the day. That the young lecturers on chemistry at these places should find time and opportunity for original research, and that sometimes of a very high order, is indeed a brilliant testimonial to their indomitable energy and resourcefulness. Overburdened with large classes until late hours at night, often in those remote and hideous parts of London which suggest to most of us only Slumland and the philanthropic efforts of Toynbee Hall or of Dr. Barnardo, these young chemists awake in the morning only to return as rapidly as possible to those laboratories which exercise on them a fascination as subtle and magnetic as that which draws the commonplace Englishman to the golf-links, the cricket field, or the racecourse. It was in the laboratory of such a technical school, the Heriot Watt College, at Edinburgh, that my distinguished predecessor in this chair, my friend Prof. Perkin, created his opportunities for devising and carrying out those now classical methods of building up carbon rings which are the admiration of all organic chemists throughout the world; methods which he has recently brought to such a pitch of perfection that he is not only able to forge these rings in great variety, but to "bridge" them with links of carbon atoms. It was at the Heriot Watt College also that his work on berberin was performed, and it was here that he contracted that fertile alliance with Dr. Kipping, his able coadjutor in so many valuable investigations.

At the London Polytechnics, again, more recently, we have had similar examples of fertility, for are we not all familiar with the masterly work of Mr. W. J. Pope, who by his investigations at the Goldsmiths' Institute has extended our knowledge of asymmetric atoms, and has shown that optical activity, which hitherto had only been associated with carbon, and somewhat doubtfully with nitrogen, can certainly be produced, not only by asymmetric pentad nitrogen, but also by tetravalent tin and sulphur? Dr. Hewitt, again, whom I am proud to number among my former students, has shown that the laboratory of the People's Palace, Whitechapel, may be made a centre in which abstruse investigations on the aromatic compounds can be carried on.

There is, however, perhaps nothing which testifies more strongly to the zeal for original investigation amongst British chemists than the manner in which some of the science masters at our schools have participated in the advancement of chemical knowledge. Some of these schools have, indeed, from time to time secured the services of men whose names are indelibly engraved on the records of scientific chemistry, and it is from the laboratories of these schools that in some cases perhaps their best work has emanated. Of the chemical investigators who have laboured in school laboratories there occur to me, amongst the living, Debus and Clowes at Queenwood, Tilden and Shenstone at Clifton, Purdie at Newcastle-under-Lyme, Brereton Baker at Dulwich, Charles Baker at Shrewsbury. To these names might be added many more; indeed an examination of the list of Fellows of the Chemical Society shows at what a number of schools throughout the country the chemical teaching is now imparted by men who have themselves advanced the science which they profess.

From the conspicuous instances which I have brought before you—and they might, did time allow, be greatly multiplied—it must be obvious that if a chemist only possesses the necessary enthusiasm and qualifications he will, no matter how inauspicious his surroundings, succeed in doing something to extend the boundaries of his science, and I think I may go further and say without fear of contradiction that in this devotion to research the chemist in this country usually throws into the shade the representatives of other branches of science. How is this pre-eminent zeal of the British chemist to be explained? I believe that there are two principal causes in operation which have brought about this result. Firstly, the great majority of the higher chemical teachers in this country have been trained in Germany, or have been trained by men who were themselves trained there; and secondly, they have only in exceptional cases been educated at the ancient seats of learning. Their inspiration and enthusiasm are almost invariably directly or indirectly traceable to a German origin, and this fire is kept alive by their remaining in constant touch with German chemical literature.

It is being continually impressed upon us in the newspapers and dinned into our ears from every platform that it is imperative for this country to approximate more to German ideas and methods, and in general to cast away our insular prejudices, obstinacy, and self-satisfaction. We chemists have already done these things; we have emancipated ourselves from the mischievous illusions which have a tendency to thrive in a country enjoying an isolated geographical position. For, during the last half century the academic springs of Germany have been visited by a stream of young English chemists, a stream which, for the perennial regularity of its flow, reminds one indeed of the pilgrimage made by our fashionable invalids to the same country in the hope of correcting the effects of high living by the waters of Homburg, Kissingen, and Wiesbaden. There must indeed be few chemists who return from the German temples of science without bringing back at least a spark of the sacred fire to be kindled on an altar at home; and although at times it may be stifled by the island fog, or burn low through the scarcity of fuel, it generally smoulders long before going out altogether.

The chemist, again, is generally, as I have said, unfettered by an English university record: he stands or falls by the work of his life, and not, as so many others do, by the reputation which they have made in three short years of adolescence at one of the ancient seats of learning.

The spirit of research, which was formerly but a sporadic manifestation within the walls of these venerable institutions, has, however, now become endemic there also, and for a number of years past chemical literature has received a continuous stream of original communications from Oxford and Cambridge, as well as from the Universities of Scotland and Ireland. Instead of those occasional contributions which were customary in the past, we have now evidence that these centres in several cases yield to none in the energy and success with which chemical investigation is being pursued, and that the work of the chemical staff is being shared in by advanced pupils trained at these universities themselves. In this connection it is quite unnecessary for me to remind you of the contributions to British Chemistry within recent years by Crum Brown and his pupils at Edinburgh, by Japp at Aberdeen, by Purdie and James Walker at the duplex university now working so harmoniously north and south of the Tay, by Emerson Reynolds at Dublin, and by Harcourt and Harold Dixon, Liveing and Dewar, Ruhemann, Heycock and Neville, Fenton, Sell, Marsh and others, who have brought our science into such living prominence on the banks of the Cam and the Isis.

It is, however, not at home only that British chemists have displayed their devotion to research, for with the world-wide relations of the empire it has naturally fallen to the lot of some of our number to carry the science to the uttermost parts of the earth, but it is surely a matter of which we may be justly proud that some of these missionaries, like Mallett, Liversidge, Pedler and Rennie, have in these distant lands carried out a number of most important scientific investigations; whilst to one of them, Dr. Divers, belongs the great distinction, not only of having carried chemistry to the Far East, but of having reared a most active school of chemical research in that fascinating island empire of the rising sun and the chrysanthemum which has won the unfeigned admiration of the West.

The annals of British Chemistry are, however, by no means an exclusive record of the exploits of those engaged in the teaching of our science. I have already referred to the importance of the contributions made by men of leisure, but an equally noteworthy feature of British Chemistry is that its progress has been so often furthered by men who have snatched the time for investigation out of a busy professional or industrial life. Belonging to this category the names of a long line of distinguished chemists of our own time suggest themselves: Warren de la Rue, Hugo Müller, Sir John Lawes, Sir William Crookes, Sir William Abney, Peter Griess, Newlands, O'Sullivan, Horace and Adrian Brown, Harris Morris, Cross, and Bevan. To this group of chemists belongs also Dr. Ludwig Mond, whose technical researches have been of such great value to industrial chemistry, whilst his devotion to the pure science is attested by his interesting discovery and investigation of the metallic carbonyl compounds, and by his conception and munificent endowment of the Davy-Faraday Laboratory, in which such unique opportunities for research have been provided by him.

This would appear to be the most fitting moment also to refer to certain other institutions intended for purposes of research which have been established during the past twenty-five years. Of these the first is the Rothamsted Laboratory, so celebrated during the last half-century for the memorable investigations of Lawes, Gilbert, Pugh, and Warington, but which has more recently, through the generosity of the late Sir John Lawes, been rendered a permanent home for the elucidation of agricultural problems both by laboratory experiments and by trials in the field. Secondly, there is the Research Laboratory which the Pharmaceutical Society has established with the view of raising to a higher level the chemical education of its most promising future members. This laboratory has furnished the opportunity for the valuable investigations of its first director, Prof. Dunstan, and of his successor, Dr. Collie. Still more recently a chemical research laboratory has been established in the Imperial Institute. That noble building has within the last few years undergone a process of transverse subdivision, one-half having assumed an independent existence as the nucleus of that still crystallising body, the University of London; whilst in the remaining half the work of the Institute is now carried on in such silence that we have almost forgotten its existence. For where is the florid music with which on summer nights the air of South Kensington was wont to reverberate? Gone. Gone also are the tea-tables, the gardens with their million fairy lights, and the promenading crowds in gay attire. But if the Institute, founded by public subscription to watch over and advance the prosperity of the British dominions, has been impoverished by the discontinuance of these revels, it has become enriched and has gained in dignity by the creation within its walls of a Research Laboratory in which Prof. Dunstan and his assistants are busily investigating the chemical nature of numerous interesting products obtained from all parts of Greater Britain.

There can, in my opinion, be no doubt that this much extended cultivation of scientific chemistry in this country, which is such a noticeable feature of the concluding years of the nineteenth century, has been greatly assisted by a most fortunate, and more or less accidental, circumstance, without which the energy and enthusiasm of our chemical teachers would have been seriously restricted in their influence. I refer to the very substantial surplus, producing an income of 6000*l.* to 7000*l.* a year, of which the Commissioners of the 1851 Exhibition found themselves possessed, and its utilisation on the advice of the late Lord Playfair for the purpose of the Research Scholarships which have for some ten years past been so highly prized by all the educational institutions permitted to participate in them. The good wrought by these scholarships has been very far-reaching, and it would be difficult to praise too highly the wisdom displayed by the Commissioners in drawing up the conditions on which they are awarded. Firstly, by not limiting them to any one science, they have stimulated a wholesome rivalry between departments to bring on their promising students to the level of scientific investigation. Secondly, they have compelled the governing bodies of educational institutions to recognise and make provision for research as part of the regular programme of these places. Thirdly, they have encouraged talented students to devote an additional year, or even more, to their education in the hope of securing one of these prizes; and these students have thus provided their teachers with the *personnel* necessary for carrying on scientific work. Fourthly, the scholars themselves have had the inestimable advantage of extending their horizon, and of coming in contact with other teachers, other schools of thought, and other views of life. Fifthly, these scholars on their return, and before they have obtained definite employment, are welcomed as supernumeraries in English colleges, where they have an opportunity of continuing their researches, and where they assist in imbuing the students with the spirit which they have themselves imbibed. Lastly, these and other scholarships of a similar character are providing the country with a body of highly trained men whose value to the nation is annually becoming more appreciated, and whose work will continue to bear fruit directly or indirectly for an indefinite period of time. These Exhibition scholarships have now been awarded since 1891, and already no fewer than sixty-five chemists, including three women, have enjoyed the enormous privilege of extending their education for a period of two, and in special cases even three, years under the most favourable surroundings.

Bearing in mind the rooted objection which pervades the people of this country to expend any public money on higher education, it is marvellous that it should have been possible to employ this fund, which after all is of a quasi-public character, for what may be described as educational use at a high potential, instead of its being dissipated in the manner so dear to Englishmen, by benefiting to an infinitesimal extent a much larger number of persons. Indeed, but for the vertebrate character of the Commissioners in 1877, the fund would have been thus frittered away, for in that year they were waited upon by a deputation of influential persons who urged that the money should be distributed in grants to provincial museums. Had that been done what would have been the result? The masses would have had a few more glass cases to gaze at on wet days and bank holidays!

There can, I think, be little doubt that in this matter of the allocation of funds intended for the public good we have reached a turning-point in the road which we have been so long pursuing. Until recently it has been the feeling of a very powerful majority in this country that public money should only be spent in such a way as to directly benefit very large numbers; and in the case of educational funds, therefore, it was only their utilisation for the benefit of the masses that could be entertained. Now, whilst it is indubitable that the improvement of our primary education was for many years a crying necessity, it has long been obvious to a minority that this policy is systematically starving that higher education in which we are lagging more and more behind those other countries in which greater elasticity prevails, and in which the immediate and obvious wants of the community receive prompt attention without regard to the traditions and doctrinaire principles of a past generation. In the matter of higher scientific education, at any rate, it is becoming more and more widely recognised that its starvation through attention being exclusively directed to the low-level education of the masses is defeating the very ends which this policy has in view. Indeed, some practical men, and even a few statesmen, realise that the many are beginning to suffer from the results which this policy has had on our manufactures and commerce, without which the multitude can have no existence at all.

The more than princely patronage of higher education by that Scotsman who has not forgotten the land of his birth during fifty years spent in a country which has afforded the necessary scope for his genius and energies illustrates the change in the wind of opinion amongst practical men; for Mr. Andrew Carnegie's handsome contribution to the funds of the University of Birmingham, and his endowment of the Universities of Scotland on a scale which is altogether without precedent, clearly show which, in his opinion, are the rungs in the educational ladder of this country that require strengthening in the interest of those very masses which it is his earnest desire to benefit. The still more recent response of the City Council of Birmingham to Mr. Chamberlain's suggestion that a rate should be levied in aid of the university of that city is further evidence that Mr. Carnegie's practically expressed opinion is shared by the enlightened rulers of that great municipality to which I have the privilege of belonging.

These, ladies and gentlemen, are, I believe, no mere sporadic manifestations, but unquestionably signs of the times. The opening of the new century is in reality a year of very serious awakening to those Englishmen who are not deaf to the voices in the air around them. It is rapidly dawning upon many that "the greatest empire which the world has ever seen" cannot be maintained unless we cast off insular prejudices and traditions, and make a careful study of those points in which other nations are our superiors, with a view to the intelligent adaptation and development, as distinguished from mere imitation, of their methods to our own particular needs.

The survey of the British chemical world at the dawn of the twentieth century affords, however, scope for satisfaction in many ways. Not only have the places in which higher chemical work can be and actually is carried on been greatly multiplied, but the number of workers has been largely increased; and although the enthusiasm of these workers cannot well be greater than that of those who laboured so successfully twenty years and more ago, it has not become diminished, and is certainly diffused more widely amongst the *personnel* of our colleges and universities. In this connection I need only remind you of the large number of active and independent investigators who are to be found amongst the members of the junior staff at almost every college in the country, and which is altogether without parallel in the past.

There are hardly any of the great problems now exercising the minds of chemists throughout the world which are not being worked at by some of our number; whilst that some chapters in the recent progress of chemical science are more or less specifically British, I would only remind you of the isolated labours of Dr. Perkin in the field of magnetic rotatory power; of Sir William Crookes's exploration of the phenomena occurring in high vacua; of the researches of Abney, Russell, and Hartley on the absorption spectra of organic compounds; of the investigations by Harold Dixon and Brereton Baker of the behaviour of substances in the complete absence of moisture; of the extension by Pope and Smiles of our knowledge of asymmetric atoms; of the near approach to the absolute zero of temperature by Dewar; and of those marvellous discoveries of Raleigh and Ramsay which have not only introduced us to five new aërial elements, but have revealed the existence of a hitherto unknown type of matter, which is apparently incapable of entering into chemical combination at all.

But whilst we may thus congratulate ourselves on this increased activity in chemical investigation, and upon the maintenance of a high standard of quality by the exceptional brilliancy of the researches of some of our number, we must now carefully consider how we stand with regard to the absolute quantity of our output.

I have called your attention to the evidence of activity in the British chemical world which is furnished by the number of original investigations communicated to the Chemical Society of London. Let me now ask you to turn to the corresponding picture, which is furnished by the statistics of the much younger Chemical Society of Berlin.

A comparison between these figures and those of the London Chemical Society shows that chemical science occupies an entirely different place in Germany from that which it even now does in this country.

Is this state of affairs to continue throughout the twentieth century? Are intellectual ambitions to be for ever subordinated to the extension of territory, to the acquisition of that metal which has had its atomic weight so accurately determined by Thorpe and Laurie, and to those other problems which fill the political horizon? Even the most recent awakening of interest in higher scientific education is not altogether of the breed to satisfy us as men of science; for the interest is assuredly not in the pursuit of knowledge for its own sake, but is aroused by the desire to secure those material advantages which it is beginning to be realised must inevitably result from the steadfast prosecution of scientific research. This is indeed a very different spirit from that which has led to the proud position occupied by science and learning of all kinds in Germany.

Schiller has truly said—

"Knowledge is to one a goddess, to another only an excellent cow."

I fear there can be no doubt that here it is the cow, and not the goddess, that is in request. Thus, whilst in Germany the love and reverence for knowledge preceded the esteem of knowledge for the material benefits which it confers, we must hope that in our country the eagerness to secure the material advantages will perhaps lead to a love and reverence for that which confers them, so that in the course of time, perhaps, the useful cow will be allotted a stall on Olympus, or be at least pastured on the grass of Parnassus.

From whatever motive, whether utilitarian or otherwise, we wish to see the position of science in this country raised, and the qualitative and quantitative output of scientific work increased, I imagine that the methods to be immediately pursued for attaining this end must be very similar.

If the higher teaching of science is to be really encouraged the first necessity is that this higher teaching shall offer a sufficiently attractive career to the man of ambition as well as to the enthusiast. We all know that the supply of enthusiasts of intellectual power combined with capacity to perform is extremely limited and wholly inadequate for carrying out the important work of the world, and that the greater part of such work is actually done by men of ambition.

In order that the academic world may attract the ablest men of ambition as well as that *rara avis*, the able enthusiast, it is necessary that the highest prizes for academic distinction should carry similar social prestige, similar remuneration, and similar opportunities of exerting public influence as are enjoyed by the leaders of other professional callings: they should be at least equal to those of the Archbishop of Canterbury or of the Lord Chancellor. It is not by any means necessary that such prizes should be numerous, as is abundantly demonstrated by the volume of able ambition which is drawn into the Church and to the Bar by the comparatively few opportunities for great success in those professions. The enthusiasts already find their way into the academic world, and, although they maintain the quality of British scientific work, they are unable, by virtue of their scarcity, to maintain the quantity which is essential for the luxuriant growth of science in our midst, whilst the absence of such tangible rewards as are bestowed in other spheres of intellectual activity prevent the importance of science being recognised by a public which has no appreciation of the inward and spiritual grace unless guided by the outward and visible sign.

Precisely the opposite policy, so far as remuneration is concerned, has, however, been pursued in the academic world during recent years, the few very moderate prizes which formerly existed having been deliberately commandeered to more nearly equalise the value of the chairs in all departments.

The principle of equalising the remuneration of different chairs is as inequitable as it is utterly unsound from a business point of view. The principle is unsound because equal salaries will not secure men of similar standing in different subjects: it is inequitable because the amount of work attaching to the chairs of different subjects is necessarily very unequal, as is the order of intellect required for the successful discharge of their duties.

Again, the system which is gaining ground in this country of allocating a certain stipend to a chair is unbusinesslike and mischievous. It is as irrational to fix the remuneration of a particular chair as it would be to fix the price to be paid for one's portrait, irrespectively of whether it were taken by a photographer or painted by a Royal Academician. If we really want the best man for any particular professional service, whether it be to treat us for a disease, to plead our cause in a court of law, or to perform on some musical instrument for our delectation, we know that we must make up our minds to pay the price which the best man commands in his particular profession, and it is absurd to suppose that the same principle does not hold good in the matter of securing the best man for an academic appointment. This, again, is intimately connected with the desirability of providing a sufficient number of steps in the academic ladder, so that it shall not be possible for the "young man of promise" to be rushed into a first-class appointment from which he has no ambition to move for the remainder of his days.

Another matter, again, requires consideration: if we are really in earnest in the attempt to bring our universities abreast of those in other countries, our chairs must be systematically thrown open to the whole world, and the best men obtainable secured, irrespectively of their nationality. Not only have small nations adopted this plan, but even the nation which is preeminent for its academic strength is by no means blind to the importance of drawing into its service from the outside men of commanding brilliance and power. I need not remind you that England has also exhibited a wise and liberal spirit in this matter in the past, and that, so far as our science is concerned, this policy has been most fully justified. For, consider only what the English Chemistry of the latter half of the nineteenth century owes to the genius and magnetic influence of the imported Hofmann. I can imagine the electors to British chairs suggesting that there might be linguistic difficulties in the way of carrying out such a policy, in answer to which I would appeal to the pupils of Hofmann to say whether his stimulating discourse lost anything of its vigour and inspiration through the strong Hessian accent with which every word of it was saturated. It is to be hoped that no narrow and short-sighted policy, disguised under that too often misused word "patriotism," will seek to close the doors of our universities to the genius and ability of other nationalities.

I believe, however, that one of the most urgent and pressing of University reforms is that greater facilities should be afforded for the migration of students from one university to another, without prejudice to their acquisition of a degree. It is the present system, which practically chains an undergraduate with links of steel to the university at which he matriculates, that is at the root of many of the evils under which our higher education is labouring.

The university at which a youth matriculates is often determined by the fatuous, although pathetic, wish of the father that his son should spend his time, I will not say work, amidst the surroundings which awaken such pleasant memories in himself; and the youth once within the magic portals has little or no opportunity of rectifying the possible mistake of his fond parent, who has probably for a quarter of a century been quite out of touch with university matters, or even divorced from the intellectual world altogether.

This foolish sentiment of loyalty to a university or even college is sometimes kept up for generations, and I have met persons who have told me that their family had always been Balliol or Trinity men, with the same sort of pride that they would doubtless have informed me, had they been able, that their ancestors came over with the Conqueror or had charged with the Cavaliers at Naseby.

The prevalence of such a sentiment shows that our universities are principally valued for their social attractions, as well as for their past history and ancient traditions, in which connection it is always well to remember that a living dog is better than a dead lion.

The possibility of students dissociating themselves from the university of their matriculation and freely migrating from one school to another would, in my opinion, not only be of immense advantage to the students themselves, enabling them to obtain the best instruction in each particular subject and greatly extending their horizon and knowledge of the world, but it would operate most favourably on the universities themselves, minimising the tendency to stagnation, and compelling those who hold the purse-strings to provide for the strengthening of weak departments. Nor should the possibilities of migration be limited to the Universities of the United Kingdom or even of the British Empire, but the prospect should be kept in view of ultimately effecting an arrangement whereby students could enjoy the advantage of visiting the universities of other countries.

Such migration is, of course, closely connected with the duration of the period of university study, and in this matter reform is most urgently needed. The traditional three years devoted to the acquisition of a degree is hopelessly inadequate for the higher purposes of university training, especially when the very immature age at which English students generally begin their university career is taken into consideration. The period of academic study should be forthwith extended to five years, as it is only in this way that the university can be effectively made a centre of research. Without a course of study of such duration, and of which research forms a part, it is quite impossible that the highly trained men who are now so urgently needed for practical avocations should be produced.

In this connection, again, we all know that much mischief has been going on in recent years. Instead of the terms on which degrees are at present obtainable being regarded as too lenient and easy, proposals are actually being put forward in some quarters to enable persons attending evening classes to thereby qualify for university degrees. Now, whilst it is of the utmost importance to provide abundant opportunities for the talented poor to obtain a university education by reducing the fees and by instituting a sufficient number of bursaries, it is imperative that those who are to be stamped with the distinctive mark of a university should have devoted their whole and undivided attention, over a certain period of time, to the courses of study prescribed. Let us beware of introducing the half-time system into the university, a system which we know to be a deplorable makeshift even in the elementary school.

In this matter of the aspirations, scope and functions of a university we have not merely to contend with the ignorance and apathy of the average Philistine, but we are wrestling against principalities, against powers and against darkness in high places. Thus only four months ago one of our most prominent statesmen, whose oracular and sporadic utterances inspire amongst millions almost the awe and respect which is felt for the supernatural, is reported in the columns of the daily papers to have said at one of the most important educational gatherings of this first year of the new century:—"You, Mr. Vice-Chancellor, spoke of the stigma that would rest on the University if it did not annually produce some work of original research. I, from another point of view, am contented if you do nothing of the kind. I am satisfied to think that in a large and increasing degree you will train men and women fit for the manifold requirements of this Empire." This statesman, who it is not surprising to find was educated at Eton and Oxford, is thus of the opinion to-day, unless, indeed, his views have changed in the interim, that it is possible to train men and women fit for the manifold requirements of this Empire without bringing, at any rate, some of them into contact with the living spirit of research—that spirit which, operating through the ages, has enabled man to transform the wilderness in which he was placed by his Creator into the garden of material and intellectual enjoyments in which that statesman was himself born.

I would ask you to contrast with the views of the distinguished *alumnus* of Eton and Oxford the utterance of another statesman who, unhampered by such educational antecedents, has formulated the following ideal for the guidance of that university which he has himself created:—

"The third feature to which I should call attention, and which, I am inclined to say, is of all the most important, is that a university should be a place where knowledge is increased, and where the limits of learning are extended. Original research, the addition of something to the total sum of human knowledge, must always be an essential part of our proposals."

Lastly, we have to consider whether this university work, in which we hope for such great developments in the twentieth century, is still to be carried on by what is virtually private enterprise and private endowment, or whether it is to be provided for by taxation.

If the reforms and developments which are being preached from so many platforms are to be really carried out, if even our higher scientific training alone is to be brought into line with that which is provided in many other countries, it is indubitable that expenditure will have to be enormously increased. Now, profoundly as we all admire the enlightened public spirit of the men and women who have in the past endeavoured out of their private resources to help forward the great movement of higher education, it is, I believe, the firm conviction of all who have any real knowledge of what this higher education means, and a clear conception of what must be done in order to put it on a proper footing in this country, that on private benefaction alone this work cannot be accomplished. But even if private endowment could raise this great edifice in our midst, it is obvious that we should have to wait indefinitely for its realisation. Voluntary contributions cannot be made to come at the bidding of those who stand in need, nor directed into the channels where they will produce the most good; they have to be patiently waited for, with the result that valuable time is lost and opportunities pass by never to return. Private benefaction, moreover, is almost always retrospective: a hospital is not founded by the charitable until the sick are dying unattended; almshouses and orphanages are not thought of until the widow and the fatherless are either starving in the streets or begging on the doorstep. What we so forcibly recognise in this matter, however, is that we have not only to make up for leeway in the past, but that we must now exercise prevision to prevent similar disastrous lapses in the future. The state of affairs to which we have been reduced must not be allowed to occur again; the warnings of those possessing special knowledge in these matters must not be disregarded in the future as they have been in the past, for it is no exaggeration that the whole of the learned societies and academic bodies of this country put together have at present a smaller corporate share of political influence than a Temperance League or a Trades Union. To what has this state of things reduced us? The humiliating spectacle of "the greatest empire the world has ever seen" at the beginning of the twentieth century without a teaching university in its metropolis, and engaged upon the task of tardily patching one together out of those heterogeneous elements of uncertain valency which are to hand. Is the completion of this structure, on a scale challenging comparison with the universities which are to be found in the other great capitals of Europe, to be delayed until a millionaire, or rather series of millionaires, can be induced to finance it? To this work, and to other works like it, is it not fitting that every inhabitant of this country should contribute? For these are works which assuredly benefit all classes, not only of this generation, but of those which are to come—at least as much as the acquisition of territory at a distance of 8000 miles from home, and for which purpose the nation is apparently willing to pay at the rate of one and a quarter million sterling per week for an indefinite period of time.

It is sometimes urged that this higher education does not benefit the masses; but could any contention be more erroneous? The poor have really a far greater stake in the prosperity of our home industries and commerce than the rich; for whilst the decay of our producing power will remove the very means of subsistence from the poor, it matters very little to many of the rich whether their dividends are derived from home-enterprises or from those of a Billion Dollar Combine or some similar transatlantic Trust or Corporation.

Higher education and true universities are also amongst the most potent factors in breaking down the hereditary stratification of society and in minimising the advantages depending upon the accident of birth, so that, with the greatly enhanced facilities which must be provided for students without means, they should afford in the future, even more than they have done in the past, an avenue for the humblest boy of talent to that position which he is by natural endowment and by his own exertion best fitted to fill in the interests of the State.

Is this great work of raising up a worthy system of national higher education, and of creating a living interest and widely diffused enthusiasm for knowledge and for the increase of knowledge in all its branches, going to be accomplished during the century of which we have but crossed the threshold? Even the most sanguine among us dare not unhesitatingly say Yes; but assuredly upon the answer, which is hidden by the veil of the inscrutable future, depends in the very highest degree, not only the material and intellectual welfare of the rising generations, but also the good name and reputation of the Empire in our own time and the gratitude which, above all things, we should strive to earn from that immortal part of us which we call Posterity.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY JOHN HORNE, F.R.S., F.R.S.E., F.G.S., PRESIDENT OF THE SECTION.

Recent Advances in Scottish Geology.

A QUARTER of a century has elapsed since the British Association met in this great industrial centre, when Prof. Young, in his presidential address to this Section, pointed out some of the difficulties which, as a teacher, he experienced in summarising the principles of geology for his students. At that meeting, also, the late Duke of Argyll. whose interest in geological questions never faded, gave an address "On the Physical Structure of the Highlands in connection with their Geological History." The return of the Association to the second city of the empire, which since 1876 has undergone remarkable development, due in no small measure to the mineral wealth of the surrounding district, suggests the question, Has Scottish geology made important advances during this interval of time? Have we now more definite knowledge of the geological systems represented in Scotland, of their structural relations, of the principles of mountain-building, of the zonal distribution of organic remains, of the volcanic, plutonic, and metamorphic rocks so largely developed within its borders? It is true that many problems still await solution, but anyone acquainted with the history of geological research must answer these questions without hesitation in the affirmative. In the three great divisions of geological investigation—in stratigraphical geology, in palæontology, in petrology—the progress has indeed been remarkable. The details of these researches are doubtless familiar to many who have taken an active share in the work, but it may serve a useful purpose, and perhaps be helpful as a landmark to give now an outline of some of the permanent advances in the solid geology of Scotland during the last quarter of a century.

The belt of Archæan gneisses and schists, which may be said to form the foundation stones of Scotland, have been mapped in great detail by the Geological Survey since 1883 along the western part of the mainland in the counties of Sutherland and Ross. In that region they occupy a well-defined position, being demonstrably older than the great sedimentary formation of Torridon Sandstone and overlying Cambrian strata. The mapping of this belt by the survey staff and the detailed study of the rocks both in the field and with the microscope by Mr. Teall have revealed the complexity of the structural relations of these crystalline masses, and have likewise thrown considerable light on their history. These researches indicate that, in the North-west Highlands, the Lewisian (Archæan) gneiss may be resolved into (1) a fundamental complex, composed mainly of gneisses that have affinities with plutonic igneous products, and to a limited extent of crystalline schists which may without doubt be regarded as of sedimentary origin; (2) a great series of igneous rocks intrusive in the fundamental complex in the form of dykes and sills.[1]

The rocks of the fundamental complex which have affinities with plutonic igneous products occupy the greater part of the tract between Cape Wrath and Skye. Mr. Teall has shown that they are essentially composed of minerals that enter into the composition of peridotites, gabbros, diorites, and granites; as, for example, olivine, hypersthene, augite (including diallage), hornblende, biotite, plagioclase, orthoclase, microcline, and quartz. In 1894 he advanced a classification of these rocks, based mainly on their mineralogical composition and partly on their structure, which has the great merit of being clear, comprehensive, and independent of theoretical views as to the history of the rock masses. Stated broadly, the principle forming the basis of classification of three of the groups is the nature of the dominant ferro-magnesian constituent, viz., pyroxene, hornblende, or biotite, while the members of the fourth group are composed of ferro-magnesian minerals without felspar or quartz ("Annual Report of the Geological Survey for 1894," p. 280). The detailed mapping of the region has shown that these rock-groups have a more or less definite geographical distribution. Hence the belt of Lewisian gneiss has been divided into three districts; the first extending from Cape Wrath to Loch Laxford; the second, from near Scourie to beyond Lochinver, and the third from Gruinard Bay to the island of Raasay. In the central area (Scourie to Lochinver) pyroxene gneisses and ultrabasic rocks (pyroxenites and hornblendites) are specially developed, while the granular hornblende rocks (hornblende gneiss proper) and the biotite gneisses are characteristic of the northern and southern tracts. These are the facts, whatever theory he adopted to explain them.

In those areas where the original structures of the Lewisian gneiss have not been effaced by later mechanical stresses it is possible to trace knots, bands, and lenticles of unfoliated, ultrabasic, and basic rocks to note the imperfect separation of the ferro-magnesian from the quartzo-felspathic constituents, to observe the gradual development of mineral banding and the net-like ramification of acid veins in the massive gneisses. Many of these rocks cannot be appropriately described as gneiss. Indeed, Mr. Teall has called attention to the close analogy between these structures and those of plutonic masses of younger date.

In the Report on Survey Work in the North-west Highlands, published in 1888, the parallel banding, or first foliation, as it was then termed, of these original gneisses was ascribed to mechanical movement (*Quart. Journ. Geol. Soc.*, vol. xliv. p. 400). But the paper on "Banded Structure of Tertiary Gabbros in Skye," by Sir A. Geikie and Mr. Teall (*ibid.*, vol. l. p. 645), throws fresh light on this question. In that region the gabbro displays the alternation of acid and basic folia, the crumpling and folding of the bands like the massive gneisses of the Lewisian complex. Obviously in the Skye gabbro the structures cannot be due to subsequent earth movements and deformation. The authors maintain that they are original structures of the molten magma, and, consequently, that much of the mineral banding of the Lewisian gneisses, as distinguished from foliation, may be due to the conditions under which the igneous magma was erupted and consolidated. Whatever theory be adopted to explain the original mineral banding of the Lewisian gneisses, it is certain that they possessed this banding, and were thrown into gentle folds before the uprise of the latter intrusive dykes.

The crystalline schists that have affinities with rocks of sedimentary origin occupy limited areas north of Loch Maree and near Gairloch. The prominent members of this series are quartz schists, mica schists, graphitic schists, limestones and dolomites with tremolite, garnet and epidote ("Annual Report of the Geological Survey for 1895," p. 17). They are there associated with a massive sill of epidiorite and hornblende schist. The relations which these altered sediments bear to the gneisses that have affinities with plutonic igneous products have not been satisfactorily determined. But the detailed mapping has proved that north of Loch Maree they rest on a platform of Lewisian gneiss, and are visibly overlain by gneiss with basic dykes (Meall Riabhach), and that both the gneiss complex and altered sediments have been affected by a common system of folds. In the field, bands of mylonised rock have been traced near the base of the overlying cake of gneiss, and the microscopic examination of the latter by Mr. Teall has revealed cataclastic structures due to dynamic movement. It is obvious, therefore, that, whatever may have been the original relations of the altered sediments to the gneiss complex, these have been obscured by subsequent earth-stresses.

The great series of later igneous rocks which pierce the fundamental complex in the form of dykes and sills is one of the remarkable features in the history of the Lewisian gneiss. In 1895 Mr. Teall advanced a classification of them (*ibid.*, p. 18), but his recent researches show that they are of a much more varied character. For our present purpose we may omit the dykes of peculiar composition and refer to the dominant types. These comprise: (1) ultrabasic rocks (peridotite), (2) basic (dolerite and epidiorite), and (3) acid (granite and pegmatite). The evidence in the field points to the conclusion that the ultrabasic rocks cut the basic, and that the granite dykes were intruded into the gneisses after the eruption of the basis dykes. The greater number of these dykes consists of basic materials. It is important to note that the basic rocks best preserve their normal dyke-like features in the central tract between Scourie and Lochinver, where they traverse the pyroxene gneisses. But southwards and northwards of that tract, in districts where they have been subjected to great dynamic movement, they appear as bands of hornblende-schist, which are difficult to separate from the fundamental complex. The acid intrusions are largely developed in the northern tract between Laxford and Durness; indeed, at certain localities in that region the massive and foliated granite and pegmatite are as conspicuous as the biotite gneisses and hornblende gneisses with which they are associated.

After the eruption of the various intrusive dykes the whole area was subjected to enormous terrestrial stresses which profoundly affected the fundamental complex and the dykes which traverse it. These lines of movement traverse the Lewisian plateau in various directions, producing planes of disruption, molecular rearrangement of the minerals and the development of foliation. It seems to be a general law that the new planes

[1] Report on the Recent Work of the Geological Survey in the North-west Highlands of Scotland based on the Field-notes and Maps of Messrs. B. N. Peach, J. Horne, W. Gunn, C. T. Clough, L. W. Hinxman, and H. M. Cadell, *Quart. Journ. Geol. Soc.*, vol. xliv. p. 387; and "Annual Report of the Geological Survey for 1894," p. 280, and 1895, p. 17.

of foliation both in the gneiss and dykes are more or less parallel with the planes of movement or disruption. If the latter be vertical or nearly horizontal the inclination of the foliation planes is found to vary accordingly.

Close to the well-defined disruption-planes, like those between Scourie and Kylesku, the gneiss loses its low angle, is thrown into sharp folds, the axes of which are parallel with the planes of movement. The folia are attenuated, there is a molecular re-arrangement of the minerals, and the resultant rock is a granulitic gneiss. Indeed, the evidence in the field, which has been confirmed by the microscopic examination of the rocks by Mr. Teall, seems to show that granulitic biotite and hornblende gneisses are characteristic of the zones of secondary shear. A further result of these earth-stresses is the plication of the original gneisses in sharp folds, trending N.W. and S.E. and E. and W.; and the partial or complete recrystallisation of the rocks along the old planes of mineral banding.

In like manner, when the basic dykes are obliquely traversed by lines of disruption, they are deflected, attenuated, and within the shear zones appear frequently as phacoidal masses amid the reconstructed gneiss. These phenomena are accompanied by the recrystallisation of the rock and its metamorphosis into hornblende schist. Similar results are observable when the lines of movement are parallel with the course of the dykes. All the stages of change from the massive to the schistose rock can be traced—the replacement of pyroxene by hornblende, the conversion of the felspar and the development of granulitic structure with foliation. Here we have an example of the phenomena developed on a larger scale by the post-Cambrian movements, viz., the production of common planes of schistosity in rocks separated by a vast interval of time, quite irrespective of their original relations. For both gneiss and dykes have common planes of foliation, resulting from earth-stresses in pre-Torridonian time.

It is important to note also that linear foliation is developed in the basic dykes where there has been differential movement of the constituents in folded areas. In the case of the anticline mapped by Mr. Clough, near Poolewe in Ross-shire, he has shown that the linear foliation is parallel with the pitch of the folds. All these phenomena tend to confirm the conclusions arrived at by Mr. Teall, and published in his well-known paper, "On the Metamorphosis of Dolerite into Hornblende Schist" (*Quart. Journ. Geol. Soc.*, vol. xli. p. 133).

The ultrabasic and acid rocks likewise occur in the schistose form, for the peridotites pass into talcose schists and the granite becomes gneissose.

In connection with the development of schistosity in these later intrusive rocks it is interesting to observe that where the basic dykes merge completely into hornblende schist, and seem to become an integral part of the fundamental complex, biotite gneisses and granular hornblende gneisses prevail. Whatever be the explanation, the relationship is suggestive.

The unconformability between the Lewisian gneiss and the overlying Torridon Sandstone, which was noted by Macculloch and confirmed by later observers, must represent a vast lapse of time. When tracing this base-line southwards through the counties of Sutherland and Ross, striking evidence was obtained by the Geological Survey of the denudation of that old land surface. In the mountainous region between Loch Maree and Loch Broom it has been carved into a series of deep narrow valleys with mountains rising to a height of 2000 feet. In that region it is possible to trace the orientation of that buried mountain chain and the direction of some of the old river courses. This remnant of Archæan topography must be regarded as one of the remarkable features of that interesting region.

In 1893 the various divisions of the Torridon Sandstone, as developed between Cape Wrath and Skye, were tabulated by the Geological Survey, which may here be briefly summarised. They form three groups: a lower, composed of epidotic grits and conglomerates, dark and grey shales with calcareous bands, red sandstones, and grits; a middle, consisting of a great succession of false-bedded grits and sandstones; an upper, comprising chocolate-coloured sandstones, micaceous flags with dark shales and calcareous bands. The total thickness of this great pile of sedimentary deposits must be upwards of 10,000 feet, and if Mr. Clough's estimate of the development of the lower group in Skye be correct, this amount must be considerably increased. Of special interest is the evidence bearing on the stratigraphical variation of the Torridon Sandstone when traced southwards across the counties of Sutherland and Ross. The lower group is not represented in the northern area, but southwards, in Ross-shire, it appears, and between Loch Maree and Sleat varies from 500 to several thousand feet in thickness. These divisions of the Torridon Sandstone are of importance in view of the correlation of certain sediments in Islay with the middle and lower Torridonian groups which there rest unconformably on a platform of Lewisian gneiss.

In continuation of the researches of Dr. Hicks, published in his paper "On pre-Cambrian Rocks occurring as Fragments in the Cambrian Conglomerates in Britain" (*Geol. Mag.*, 1890, p. 516), Mr. Teall has specially investigated the pebbles found in the Torridon Sandstone. The local basement breccias of that formation have doubtless been derived from the platform of Lewisian gneiss on which they rest, but the pebbles found in the coarse arkose tell a different story ("Annual Report of the Geological Survey for 1895," p. 20). He has found that they comprise quartzites showing contact alteration, black and yellow cherts, jaspers with spherulitic structures which indicate that they have been formed by the silification of liparites of the "Lea-rock" type and spherulitic felsites that bear a striking resemblance to those of Uriconian age in Shropshire. These interesting relics have been derived from formations which do not now occur anywhere in the western part of the counties of Sutherland and Ross, and they furnish impressive testimony of the denudation of the Archæan plateau in pre-Torridonian time.

These Torridonian sediments, like the sandstones of younger date, contain lines of heavy minerals, such as magnetite, ilmenite, zircon, and rutile ("Annual Report of the Geological Survey for 1893," p. 263). The dominant felspar of the arkose group is microcline, that of the basal group oligoclase. In the calcareous sediments of the upper and lower groups fossils might naturally be expected, but the search so far has not been very successful. Certain phosphatic nodules have been found in dark micaceous shales of the upper group which have been examined by Mr. Teall. From their chemical composition these nodules might be regarded as of organic origin; but he has found that they contain spherical cells with brown-coloured fibres, which appear to be débris of organisms (*ibid.*, 1899, p. 185).

Early in last century the Torridonian deposits were referred by Macculloch (*Trans.* Geol. Soc., ser. 1, vol. ii. p. 450; "The Western Isles of Scotland," vol. ii. p. 89) and Hay Cunningham (*Transactions* of the Highland and Agricultural Society of Scotland, vol. xiii. 1839) to the "Primary Red Sandstone," and by Murchison (*Trans.* Geol. Soc., ser. 2, vol. iii. p. 155), Sedgwick, and Hugh Miller to the Old Red Sandstone. The structural relations of the Torridon Sandstone to the overlying series of quartzites and limestones were first clearly shown by Prof. Nicol (*Quart. Journ. Geol. Soc.*, vol. xiii. p. 17), who traced the unconformability that separates them for 100 miles across the counties of Sutherland and Ross. When Salter pointed out the Silurian facies of the fossils found in the Durness limestone by Mr. Charles Peach, the Torridonian formation was correlated with the Cambrian rocks of Wales by Murchison (*ibid.*, vol. xv. p. 353). The discovery of the *Olenellus* fauna, indicating the lowest division of the Cambrian system, in the quartzite-limestone series by the Geological Survey in 1891 (*ibid.*, vol. xlviii. p. 227) demonstrated the pre-Cambrian age of the Torridon Sandstone. In view of that discovery, which proves the great antiquity o. the Torridonian sediments, it is impossible to climb those picturesque mountains in Assynt or Applecross without being impressed with the unaltered character of these deposits. Yet it can be shown that under the influence of post-Cambrian movements they approach the type of crystalline schists.

Before proceeding to the consideration of the Durness series of quartzites and limestones and their relations to the Eastern Schists, brief reference must be made to the controversy between Murchison and Nicol regarding the sequence of the strata.

The detailed mapping of the belt between Eriboll and Skye by the Geological Survey has completely confirmed Nicol's conclusions (1) that the limestone is the highest member of the Durness series; (2) that the so-called "Upper Quartzite" and "Upper Limestone" of Murchison's sections are merely the repetition of the lower quartzite and limestone due to faults or folds; (3) that there is no conformable sequence from the quartzites and limestones into the overlying schists and gneiss; (4) that the line of junction is a line of fault indicated by proofs of fracture and contortion of the strata. It is true that in the course of his investigations Nicol's views underwent a process of evolution, and that even in the form in which he ultimately presented them he did not grasp the whole truth. We now know that he was in error when he regarded portions of the Archæan gneiss, occurring in the displaced masses, as igneous rocks intruded during the earth-movements, and that he failed to realise the evidence bearing on dynamic metamorphism resulting from these movements. But I do not doubt that the verdict of the impartial historian will be that Nicol displayed the qualities of a great stratigraphist in grappling with the tectonics of one of the most complicated mountain chains in Europe.

The period now under review embraces the reopening of that controversy in 1878 by Dr. Hicks, and its close in 1884 after the publication of the "Report on the Geology of the North-west of Sutherland," by the Geological Survey (NATURE, vol. xxxi. p. 29, November 1884). The Survey work has confirmed Prof. Bonney's identification of the Lewisian gneiss and Torridon Sandstone in Glen Logan, Kinlochewe (*Quart. Journ. Geol. Soc.*, vol. xxxvi. p. 93), brought into that position by a reversed fault; and Dr. Callaway's conclusions regarding overthrust faulting at Loch Broom, in Assynt and in Glencoul (*ibid.*, vol. xxxix. p. 416). Special reference must be made to the remarkable series of papers by Prof. Lapworth on "The Secret of the Highlands," in which he demonstrated the accuracy of Nicol's main conclusions, and pointed out that the stratigraphical phenomena are but the counterpart of those in the Alps, as described by Heim (*Geol. Mag.*, December 2, vol. x. pp. 120, 193, 337). His researches, moreover, led him to a departure from Prof. Nicol's views regarding the age, composition, and mode of formation of the Eastern Schists, for in the paper which he communicated to the Geologists' Association in 1884 he announced that their present foliated and mineralogical characters had been developed by the crust-movements which operated in that region since the time of the Durness quartzites and limestones (*Proc.* Geol. Assoc., vol. viii. p. 438; *Geol. Mag.*, December 3, vol. ii. 1885, p. 97). Allusion must be made also to his great paper "On the Discovery of the *Olenellus* Fauna in the Lower Cambrian Rocks of Britain," in which he not only chronicled the finding of this fauna at the top of the basal quartzite in Shropshire, but suggested the correlation of the Durness quartzites and limestones with the Cambrian rocks elsewhere (*Geol. Mag.*, December 3, vol. v. pp. 484–487). That suggestion was strikingly confirmed within three years afterwards by the discovery of the *Olenellus* fauna in Ross-shire.

The detailed mapping of the belt of Cambrian strata has proved the striking uniformity of the rock sequence. There is little variation in the lithological characters or thicknesses of the various zones. Basal quartzites, pipe-rock, Fucoid-beds, Serpulite (*Salterella*) grit, limestone, and dolomite form the invariable sequence, for a distance of a hundred miles, to the west of the line of earth-movements. This feature is also characteristic of the fossiliferous zones, for the sub-zones of the pipe-rock, the *Olenellus* fauna in the Fucoid-beds, and the *Salterella* limestone have been traced from Eriboll to Skye. Owing to the interruption of the sequence by reversed faults or thrusts, the higher fossiliferous limestone zones are never met with between Eriboll and Kishorn, but they occur in Skye, where they were first detected by Sir A. Geikie (*Quart. Journ. Geol. Soc.* vol. xliv. p. 62).

Regarding the palæontological divisions of the system, my colleague, Mr. Peach, concludes "that the presence of three species of *Olenellus* in the Fucoid-beds and Serpulite-grit of the North-west Highlands, nearly allied to the American form *Olenellus Thomsoni*—the type species of the genus—together with *Hyolithes*, *Salterella*, and other organisms found with it, prove that these beds represent the Georgian terrane of America, which, as shown by Walcott, underlies the *Paradoxides* zone." Hence he infers that there can be no doubt of the Lower Cambrian age of the beds yielding the Olenellus fauna in the North-west Highlands. Mr. Peach further confirms Salter's opinion as to the American facies of the fossils obtained from the higher fossiliferous zones of the Durness dolomite and limestone. He states that "the latter fauna is so similar to, if not identical with, that occurring in Newfoundland, Mingan Islands, and Point Levis, beneath strata yielding the *Phyllograptus* fauna of Arenig age, that the beds must be regarded as belonging to the higher divisions of the Cambrian formation."

The intrusive igneous rocks of the Assynt region, of later date than Cambrian time, and yet older than the post-Cambrian movements, have been specially studied by Mr. Teall, who has obtained results of special importance from a petrological point of view. This petrographical province embraces the plutonic complex of Cnoc na Sroine and Loch Borolan, and the numerous sills and dykes that traverse the Cambrian and Torridonian sediments, and even the underlying platform of Lewisian gneiss. He infers that the plutonic rocks have been formed by the consolidation of alkaline magmas rich in soda. At the one end of the series is the quartz-syenite of Cnoc na Sroine, and at the other the basic augite-syenite, nepheline-syenite, and borolanite. The basic varieties occur on the margin, and the acid varieties in the centre. The sills and dykes comprise two well-marked types, camptonites or vogesites, and felsites with alkali felspar and ægirine, which he believes to represent the dyke form of the magmas that gave rise to the plutonic mass (*Geol. Mag.*, December 4, vol. vii. p. 385, 1900).

The striking feature in the geology of the North-west Highlands is the evidence relating to those terrestrial movements that affected that region in post-Cambrian times, which are without a parallel in Britain. The geological structures produced by these displacements are extremely complicated, but the vast amount of evidence obtained in the course of the survey of that belt clearly proves that, though the sections vary indefinitely along the line of complication, they have certain features in common which throw much light on the tectonics of that mountain chain. Some of these features may thus be briefly summarised.

(1) By means of lateral compression or earth-creep the strata are thrown into a series of inverted folds which culminate in reversed faults or thrusts.

(2) Without incipient folding, the strata are repeated by a series of minor thrusts or reversed faults which lie at an oblique angle to the major thrust-planes and dip in the direction from which the pressure came, that is, from the east.

(3) By means of major thrusts of varying magnitude the following structures are produced: (*a*) the piled-up Cambrian strata are driven westwards along planes formed by the underlying undisturbed materials; (*b*) masses of Lewisian gneiss, Torridon Sandstone, and Cambrian rocks are made to override the underlying piled-up strata; (*c*) the Eastern Schists are driven westwards and, in some cases, overlap all major and minor thrusts till they rest directly on the undisturbed Cambrian strata.

When to these features are added the effects of normal faulting and prolonged denudation, it is possible to form some conception of the evolution of those extraordinary structures which are met with in that region. Some of the features just described occur in other mountain chains affected by terrestrial movement, as in the Alps and in Provence; but there is one which appears to be peculiar to the North-west Highlands. It is the remarkable overlap of the Moine Thrust-plane—the most easterly of the great lines of displacement. Along the southern confines of the wild and complicated region of Assynt, that plane can be traced westwards for a distance of six miles to the Knockan cliff, where the micaceous flagstones rest on the Cambrian limestone. In Durness we find an outlier of the Eastern Schists reposing on Cambrian limestone, there preserved by normal faults, at a distance of about ten miles from the mass of similar schists east of Loch Eriboll, with which it was originally continuous.

Though many of these structures appear incredible at first, it is worthy of note that some have been reproduced experimentally by Mr. Cadell (*Trans.* Roy. Soc. Edinburgh, vol. xxxv. p. 337). He took layers of sand, loam, clay, and plaster of Paris, and after the materials had set into hard brittle laminæ, in imitation of sedimentary strata, he applied horizontal pressure under varying conditions. The results, some of which may here be given, were remarkable.

(1) The compressed mass tends to find relief along a series of gently inclined thrust-planes, which dip towards the side from which pressure is exerted.

(2) After a certain amount of heaping up along a series of minor thrust-planes, the heaped-up mass tends to rise and ride forward bodily along major thrust-planes.

(3) The front portion of a mass being pushed along a thrust-plane tends to bend over and curve under the back portion.

(4) A thrust-plane below may pass into an anticline above; and a major thrust-plane above may and probably always does originate in a fold below.

Now these important experiments confirm the conclusion reached by the Geological Survey from a study of the phenomena in the field, viz., that under the influence of horizontal compression or earth-creep the rocks in that region behaved like brittle rigid bodies which snapped across, were piled up and driven westwards in successive slices. But, further, these displacements were accompanied by differential movement of the materials which resulted in the development of new structures. These phenomena culminate along the belt of rocks in immediate association with the Moine Thrust, where the outcrop of that thrust lies to the east of a broad belt of displaced materials. There, Lewisian gneiss, Torridon Sandstone, and Cambrian quartzite are sheared and rolled out, presenting new divisional planes parallel with that of the Moine Thrust. The Lewisian gneiss shades into flaser gneiss and schist, and ultimately passes into a banded rock like a platy schist. The pegmatites show fluxion structure with felspar "eyes" like that of the rhyolites. At intervals in these zones of highly sheared rocks, phacoidal masses of Lewisian gneiss appear, in which the pre-Torridonian structures are not wholly effaced. The sills of camptonite and felsite intrusive in the Cambrian rocks become schistose and together with the sediments in which they occur appear in a lenticular form. All these mylonised rocks show a characteristic striping on the divisional planes, due to orientation of the constituents in the direction of movement.

Still more important evidence in relation to the question of regional metamorphism is furnished by the Torridon Sandstone. In the case of the basal conglomerate the pebbles have been flattened and elongated, and a fine wavy structure has been developed in the matrix. In the district of Ben More, Assynt planes of schistosity, more or less parallel with the planes of the Ben More Thrust, pass downwards from the Torridon conglomerate into the underlying gneiss. Both have a common foliation irrespective of the unconformability between them. Again, along the great inversion south of Stromeferry, foliation has been developed in the Torridon conglomerate and overlying Lewisian gneiss, parallel to the plane of the Moine Thrust. The Torridon grits and sandstones south of Kinlochewe and between Kishorn and Loch Alsh are similarly affected by the post-Cambrian movements. Mr. Teall has shown that the quartz grains have been drawn out into lenticles and into thin folia that wind round "eyes" of felspar. A secondary crypto-crystalline material has been produced, sericitic mica appears in the divisional planes, and in some instances biotite is developed. In short, he concludes that in these deformed Torridonian sediments there is an approximation to the crystalline schists of the Moine type. The stratigraphical horizon of these rocks can be clearly proved. The subdivisions of the Torridon Sandstone have been recognised in those displaced masses which lie to the east of the Kishorn Thrust and to the west of the Moine Thrust. It is worthy of note also that in the belt of highly sheared gneiss south of Stromeferry that comes between the Torridonian inversion in the west and the Moine Thrust on the east, Mr. Peach has found folded and faulted inliers of the basal division of the Torridon Sandstone that have a striking resemblance to typical Moine schists.

Regarding the age of these post-Cambrian movements, it is obvious that they must be later than the Cambrian limestone and older than the Old Red Sandstone, for the basal conglomerates of the latter rest unconformably on the eastern schists and contain pebbles of basal quartzite, pipe-rock, limestone, and dolomite derived from the Cambrian rocks of the North-west Highlands.

East of the Moine Thrust or great line of displacement extending from Eriboll to Skye, we enter the wide domain of the metamorphic rocks of the Highlands, a region now under investigation, and which presents difficult problems for solution. Two prominent types of crystalline schists (Caledonian series, Callaway, and Moine schists of the Geological Survey) have been traced over wide areas in the counties of Sutherland, Ross, and Inverness, and across the Great Glen to the northern slopes of the Grampians. Consisting of granulitic quartzose schists and muscovite-biotite schist or gneiss, they appear to be of sedimentary origin, though crystalline. They are associated with recognisable masses of Lewisian gneiss covering many square miles of ground and presenting many of the structures so characteristic of that complex in the undisturbed areas already described. Within the belt of Lewisian gneiss at Glenelg Mr. Clough has mapped a series of rocks presumably of sedimentary origin, including graphitic schists, mica schists, and limestones, but the gneiss with which they are associated possesses granulitic structure like that of the adjoining Moine schists ("Summary of Progress of the Geological Survey for 1897," p. 37). Further, in the east of Sutherland, and also in the county of Ross, foliated and massive granites appear which are interleaved in the adjoining Moine schists, forming injection gneisses and producing contact metamorphism.[1]

In the Eastern Highlands the Moine series disappears and is replaced by a broad development of schists, admittedly of sedimentary origin, which have been termed the Dalradian series by Sir A. Geikie. Within recent years it has been divided into certain rock-groups which have been traced by the Geological Survey from the counties of Banff and Aberdeen to Kintyre. It has been found that, though highly crystalline in certain areas, they pass along the strike into comparatively unaltered sediments, as proved by Mr. Hill in the neighbourhood of Loch Awe ("Annual Report of the Geological Survey for 1893," p. 265). Before the planes of schistosity were developed in these Dalradian schists they were pierced by sills of basic rock (gabbro and epidiorite) and acid material (granite), both of which must have shared in the movements that affected the schists, as they merge respectively into hornblende schists and foliated granite or biotite gneiss. Both seem to have developed contact metamorphism; indeed, Mr. Barrow[2] contends that the regional metamorphism so prominent in the south-east Highlands is mainly, if not wholly, due to the intrusion of an early granite magma, now exposed at the surface in the form of local bosses of granite and isolated veins of pegmatite.

The age of the Dalradian schists has not been determined. Though there seems to be an apparent order of superposition, in this series it is still uncertain whether that implies the original sequence of deposition. Since Sir A. Geikie applied the term Dalradian to the Eastern Highland schists in 1891 (*Quart. Journ. Geol. Soc.*, vol. xlvii. p. 72), evidence has been obtained ("Annual Report of the Geological Survey for 1893," p. 266; for 1895, p. 25; for 1896, p. 27) that suggests the correlation of certain rocks along the Highland border with the Arenig and younger Silurian strata of the Southern Uplands. Consisting of epidiorite, chlorite schist, radiolarian cherts, black shales, grits, and limestone, they have been traced at intervals from Arran to Kincardineshire. In the latter region Mr. Barrow contends that they are separated by a line of disruption from the Highland schists to the north; but no such discordance has been detected in the Callander district or in Arran. Though these rocks of the Highland border have been much deformed, yet their occurrence in the same order of succession in that region and in the Southern Uplands is presumptive evidence for their correlation.

In view of this evidence it is not improbable that the Dalradian series may contain rock-groups belonging to different geological systems. Indeed, the result of recent Survey work in Islay tends to support this view. For in the south-west part of that island there is a mass of Lewisian gneiss overlaid unconformably by sedimentary strata which have been correlated with the lower and middle divisions of the Torridon Sandstone. Unfortunately the sequence ends here, as both the gneiss and overlying sediments are separated by a line of disruption or thrust-plane from the strata in the eastern part of the island. And yet, notwithstanding this break, the evidence obtained in the latter district is remarkable, whatever theory be adopted to explain it. There the Islay limestone and black slates appear to be covered unconformably by the Islay quartzite containing Annelid tubes and followed in ascending sequence by Fucoidal shales and dolomites, suggestive of the Cambrian succession in Sutherland and Ross. The Islay quartzite passes into Jura, thence to the mainland, and it may eventually prove to be the Perthshire quartzite, while the Islay limestone and black slate are supposed to be the prolongations of the limestone and slate of the Loch Awe series in Argyllshire ("Summary of Progress for 1899," p. 66).

From the foregoing data it will be seen that much uncertainty prevails regarding the age and structural relations of the metamorphic rocks of the Highlands, but the difficulties that here confront the observer are common to all areas affected by regional metamorphism.

A prominent feature in the geology of the Eastern Highlands is the great development of later plutonic rocks chiefly in the

1 "On Foliated Granites and their Relations to the Crystalline Schists in Eastern Sutherland" (*Quart. Journ. Geol. Soc.*, vol. lii. p. 633).

2 "Intrusion of Muscovite-biotite Gneiss in the South-east Highlands and its accompanying Metamorphism" (*Quart. Journ. Geol. Soc.*, vol. xlix. p. 330).

form of granite ranging along the Grampian chain from Aberdeenshire to Argyllshire. In connection with one of these masses a remarkable paper appeared in 1892 which in my opinion has profoundly influenced petrological inquiry in Scotland from the light which it threw on the relations of a connected series of petrographical types in a plutonic complex. I refer to the paper on the "Plutonic Rocks of Garabal Hill and Meall Breac," by Mr. Teall and Mr. Dakyns (*Quart. Journ. Geol. Soc.*, vol. xlviii. p. 104).

The authors showed that this plutonic mass comprises granite, tonalite, augite-diorite, picrites, serpentine, and other compounds. Mr. Teall regards the members of this sequence as products of one original magma by a process of differentiation, the peridotites being the oldest rocks, because the minerals of which they are composed are the first to form in a plutonic magma. As the process of consolidation advances, rocks of a varied composition arise, in the order of increasing acidity, viz., diorites, tonalites, and granites. The most acid rock consists of quartz and orthoclase, which may represent the mother liquor after the other constituents had separated out. Mr. Teall concludes that progressive consolidation of one reservoir gives rise to the formation of magmas of increasing acidity, and hence that basic rocks should precede the acid rocks. This theory of magmatic differentiation—so strenuously advocated by Brögger, Vogt, Rosenbusch, Iddings, Teall, and others—was first applied to the interpretation of varied types of plutonic masses in Scotland by Mr. Teall in the paper referred to. Since then he has extended its application to the granite masses in the Silurian tableland of the south of Scotland, which include rocks, ranging from hyperites at the one end to granitite with microcline, and aplite veins at the other.[1] Many of the phenomena presented by the newer granite masses of the Eastern Highlands seem to lend support to this theory. These views, indeed, have permeated the petrological descriptions of the granitic protrusions in the counties of Aberdeen and Argyll which have been given by Messrs. Barrow, Hill, Kynaston, and Craig[2] in recent years.

One of the remarkable advances in Scottish geology during the period under review is the solution of the order of succession and tectonic relations of the Silurian rocks of the south of Scotland by Prof. Lapworth. The history of research relating to that tableland, and of all his contributions to the problems connected with it, has been given in detail in the recent volume of the Geological Survey on that formation. At present it will be sufficient to refer to his three classic papers, which, in my opinion, record one of the great achievements in British geology. The first, on "The Moffat Series" (*Quart. Journ. Geol. Soc.*, vol. xxxiv. p. 240), demonstrated, by means of the vertical distribution of the graptolites, the order of succession in those fine deposits (black shales and mudstones), which were laid down near the verge of sedimentation, and are now exposed in anticlinal folds in the central belt. The second, on "The Girvan Succession" (*ibid.*, vol. xxxviii. p. 537), showed how certain graptolite zones of the Moffat shales are interleaved, in the Girvan region, with conglomerates, grits, sandstones, flagstones, mudstones, shales, and limestones, charged with all the varied forms of life found in shallow seas or near shore. In the third, on "The Ballantrae Rocks of the South of Scotland and their Place in the Upland Sequence" (*Geol. Mag.*, December 3, vol. vi. p. 20), he indicated the distribution and variation of the Moffat terrane (Upper Llandeilo to Upper Llandovery) and of the Gala terrane (Tarannon), which form the greater part of the uplands. He further pointed out how the rocks and the fossils vary across the uplands according to the conditions of deposition. Finally he proved that the complicated tectonics of the Silurian tableland, its endless overfolds, its endoclinal and exoclinal structures, can be unravelled by means of the graptolite zones. These researches disposed of the order of succession based on Barrande's doctrine of Colonies, and established the zonal value of graptolites as an index of stratigraphical horizons. So complete was the zonal method of mapping adopted by Prof. Lapworth, and so accurate were his generalisations, that few modifications have been made in his ork.

1 "Annual Report of the Geological Survey for 1896," p. 40; see also "The Silurian Rocks of Scotland" (Geological Survey Memoir, 1899, p. 607).

2 "Annual Report of the Geological Survey for 1897," p. 87; for 1898, pp. 25–28; see also paper on "Kentallenite and its Relations to other Igneous Rocks in Argyllshire" (*Quart. Journ. Geol. Soc.*, vol. lvi. p. 531).

In the course of the re-examination of the Silurian tableland by the Geological Survey some important additions were made to our knowledge of the Silurian system as there developed. Underlying all the sediments of the uplands there is a series of volcanic and plutonic rocks of Arenig age, the largest development of which occurs at Ballantrae in Ayrshire, where their igneous character was recognised by Prof. Bonney. But they appear in the cores of numerous anticlines over an area of about 1500 square miles, forming one of the most extensive volcanic areas of Palæozoic age in the British Isles. These volcanic rocks are overlain by a band of cherts and mudstones, succeeded by black shales yielding Glenkiln graptolites of Upper Llandeilo age. The cherts, which are abundantly charged with Radiolaria, implying oceanic conditions of deposition, are about 70 feet thick, and have been traced over an area of about 2000 square miles. The deposition of the Radiolarian ooze must have occupied a long lapse of time. Indeed the cherts and mudstones represent the strata which, in other regions, form the Upper Arenig and Lower Llandeilo divisions of the Silurian system. They furnish interesting evidence of the oceanic conditions which here prevailed in early Silurian time, and form a natural sequel to Prof. Lapworth's researches bearing on the graptolitic deposits of the Upper Llandeilo period, which must have been laid down on the sea-floor near the limit of the land-derived sediment.

Of special interest is the new fish fauna found by the Geological Survey in the Ludlow and Downtonian rocks between Lesmahagow and Muirkirk, which the researches of Dr. Traquair have shown to be of great biological and palæontological value (*Trans.* Roy. Soc. Edin., vol. xxxix. p. 827). This discovery has enabled him to give a new classification of the *Ostracodermi*, to enlarge the order of the ***Heterostraci***, which now includes four families, instead of the ***Pteraspidae*** alone. He has further shown that the *Coelolepidae* were not Cestraciont sharks to which the *Onchus* spines belonged, but ***Heterostraci***, though probably of Elasmobranch origin, judging from the shagreen-like scales. The *Coelolepidae* are common fishes in the Ludlow and Downtonian rocks of Lanarkshire. The genus, *Thelodus*, first described by Agassiz from detached scales in the Ludlow bone-bed, and subsequently figured and described by Pander and Rohon from scales in the Upper Silurian rocks of Oesel, is here represented for the first time by nearly complete forms. But it is remarkable that no *Onchus* spines, nor any *Pteraspidae*, nor *Cephalaspidae* have been found in the Lanarkshire strata, the nearest related genus to *Cephalaspis* being *Atelcaspis*, which, however, represents a distinct family.

The group of sandstones, conglomerates, shales, and mudstones that form the passage-beds between the Ludlow rocks and the Lower Old Red Sandstone in Lanarkshire are now regarded as the equivalents of the Downtonian strata in Shropshire, and are linked with the Silurian system. The mudstones of this group, containing the new fish fauna, likewise yield ostracods, phyllocarid crustaceans, and eurypterids—forms which connect these beds with the underlying Ludlow rocks. The band of greywacke-conglomerate, that extends from the Pentland Hills into Ayrshire, composed largely of pebbles derived from the Silurian tableland, is now taken as the base line of the Lower Old Red Sandstone on the south side of the great midland valley of Scotland.

The period under review has been marked by important additions to our knowledge of the Old Red Sandstone formation. In 1878 appeared a valuable monograph by Sir Archibald Geikie on "The Old Red Sandstone of Western Europe" (*Trans.* Roy. Soc. Edin., vol. xxviii. p. 345), by far the most important treatise on this subject since the publication of Hugh Miller's classic work published in 1841. Following up the view maintained by Fleming, Godwin-Austen, and Ramsay, that the deposits of this formation were laid down in lakes or inland seas, he defined the geographical areas of the various basins in the British area, giving to each a local name. He gave an outline of the development of the rocks north of the Grampians, in Caithness, Orkney, and Shetland. He advanced an ingenious argument in favour of correlating the Caithness flagstone series (middle division, Murchison) with the Lower Old Red Sandstone south of the Grampians. He contended that "the admitted palæontological distinctions between the two areas are probably not greater than the striking lithological differences between the strata would account for, or than the contrast between the ichthyic faunas of adjacent but disconnected water basins at the present time." Sir A. Geikie further gave a table showing the vertical range of the known fossils of the Caithness series from data partly supplied by the late Mr. C. Peach.

During the last quarter of a century Dr. Traquair has made a special study of the ichthyology of the Old Red Sandstone and Carboniferous strata of Scotland, which has enabled him to throw much light on the distribution of fossil fishes in these rocks and on their value for the purpose of correlation. His researches show that the fish fauna of the formation south of the Grampians resembles that of the Lower Old Red Sandstone of the West of England and adjoining part of Wales in the abundance of specimens of *Cephalaspis*, the common species in Forfarshire (*C. Lyelli*, Ag.) being also indistinguishable from that in the Herefordshire beds. *Pteraspis* occurs in both regions, though of different species. Of Acanthodians *Parexus recurvus*, Ag., occurs in both, together with *Climatius* (*C. ornatus*, Ag.). The abundance of *Cephalaspis* (*C. Campbelltonensis*, Whit., *C. Jexi*, Traq.) and of *Climatius* spines is characteristic of the Lower Devonian rocks of Canada.

The Old Red Sandstone of Lorne has recently yielded organic remains, akin to those found in Forfarshire, south of the Grampians, viz., *Cephalaspis Lornensis*, Traq., two species of myriapods (*Campecaris Forfarensis* and a species of *Archidesmus* ("Summary of Progress, Geological Survey, 1897," p. 83).

In the deposits of Lake Orcadie, north of the Grampians, quite a different fish fauna from that of Forfarshire appears. Dr. Traquair has noted that there are no species common to the two areas, and only two genera, viz., *Mesacanthus* and *Cephalaspis*. The latter genus is, however, represented in Caithness only by a single specimen of a species (*C. magnifica*, Traq.) different from any found elsewhere. It might here be observed that *Cephalaspis* is represented also in the Upper Devonian rocks of Canada by a single specimen of a peculiar species (*C. laticeps*, Traq.), and hence Dr. Traquair has shown that, though *Cephalaspis* is most abundant in the Lower Devonian, it extends also into the upper division of that system. It further appears that *Osteolepidae* (*Osteolepis*, *Diplopterus*), *Rhizodontidae* (*Tristichopterus*, *Gyroptychius*), *Holoptychiidae* (*Glytolepis*), *Asterolepidae* (*Pterichthys*, *Microbrachius*), *Ctenodontidae* (*Dipterus*) are abundant in the Orcadian fauna, none of which has occurred in the Lower Old Red Sandstone of Forfarshire, the West of England, or in the Lower Devonian rocks of Canada. Dr. Traquair recognised, however, the identity of the fishes from the well-known fish band in the basin of the Moray Firth with those brought from the west part of Orkney, though these forms did not quite agree with the fossils from the Thurso district. He subsequently found that the fish fauna from the Orcadian beds in the Moray Firth basin is represented in Caithness by that of Achanarras; and, further, that two other faunas occur in the Caithness area—that of Thurso and that of John o' Groats as given below:—

John o' Groats...	*Tristichopterus alatus*, Egert.
	Microbrachius Dicki, Traq.
Thurso ...	*Coccosteus minor*, H. Miller.
	Thursius pholidotus, Traq.
	Osteolepis microlepidotus, Pander.
Achanarras ...	*Pterichthys*, 3 species.
	Cheirolepis Traillі, Ag.
	Osteolepis macrolepidotus, Ag.

In 1898 appeared an important paper by Dr. Flett on "The Old Red Sandstone of the Orkneys" (*Trans.* Roy. Soc. Edin., vol. xxxix. p. 383), in which he described the results of his detailed examination of the islands. He proved the existence there of three fish faunas, and their correspondence with those identified in Caithness by Dr. Traquair. From the evidence in the field he adopted the following order of succession and correlation of the strata:—

3. Eday Sandstones and John o' Groats beds.
2. Rousay and Thurso beds.
1. Stromness, Achanarras, and Cromarty beds.

A further important result of Dr. Flett's researches in the Old Red Sandstone of these northern isles was communicated to the Royal Society of Edinburgh this year. He has found in the Shetland beds, which had previously yielded no fossils save plants, fragments, identified by Dr. Traquair as *Holonema*, a fish new to Britain, but occurring in the Chemung group of North America, the subdivision of the Upper Devonian that immediately underlies the Catskill red sandstones, with remains of *Holoptychius*. Dr. Traquair has also recognised in Dr. Flett's collection fragments of *Asterolepis*, a genus characteristic of the Upper Old Red Sandstone, and which, as proved by Dr. Flett, occurs in the "Thurso beds" of the Orkneys. The interest attaching to this discovery is very great, for Dr. Flett contends that it indicates a fourth life-zone in the Orcadian series, and, further, that it tends to span the break between the Orcadian division and Upper Old Red Sandstone.

In the Upper Old Red Sandstone on the south side of the Moray Firth, Dr. Traquair recognised two life-zones, and subsequently, with the assistance of Mr. Taylor, Lhanbryde, a third, in the following order. The lowest is that of the Nairn sandstones with *Asterolepis maxima*, Ag.; the second, that of Alves and Scaat Craig with *Bothriolepis major*, Ag., *Psammosteus Taylori*, Traq.; and the highest that of Rosebrae, the fauna of which, according to Dr. Traquair, has a striking resemblance to the assemblage in the Dura Den Sandstones in Fife.

Before 1876 all the Carboniferous areas in the great midland valley of Scotland had been mapped by the Geological Survey. The extent and structural relations of the various coal-fields were determined according to the information then available, and shown in the published maps. But the rapid development of certain fields in the east of Scotland necessitated a revision of them which has lately been done. The Fife coal-field has been re-examined by Sir A. Geikie, Mr. Peach and Mr. Wilson, and the oil-shale fields in the Lothians have been mapped by Mr. Cadell. An important memoir by Sir A. Geikie on "The Geology of Central and Western Fife and Kinross" has just been issued by the Geological Survey, in which the structure of these coal-fields is described. Mr. Cadell lately gave an account of the geological structure of the oil-shale fields in his presidential address to the Edinburgh Geological Society.

Within the period under review detailed researches of great importance on the fossil flora of British Carboniferous rocks have been carried out by Mr. Kidston, to which reference ought to be made. The results are of the highest value for correlating the strata in different areas.[1] By means of the plants he arranges the Carboniferous rocks of Scotland in two great divisions: a lower, comprising the Calciferous Sandstone and Carboniferous Limestone series; and an upper, including the Millstone Grit and the Coal-measures, there being a marked palæontological break at the base of the Millstone Grit. He shows that the upper and lower divisions of the system, not only in Scotland but in Britain, are characterised by a different series of plants, not one species passing from the lower division—save in the case of *Stigmaria*—into the upper. From his researches it appears that, among ferns, *Neuropteris* is all but unknown in the lower division, whereas in the upper it is very abundant. The *Sphenopterids* are proportionately common in both divisions; but those of the lower are usually characterised by cuneate segments, while those of the upper have generally rounded pinnules. *Alethopteris*, so common throughout the whole of the upper series, is entirely absent from the lower. The genus *Calamites*, which is extremely plentiful in the upper, is almost entirely absent from the lower division, where its place is taken by *Asterocalamites*. The *Cordaiteae* are also rare below the Millstone Grit, though very plentiful above that horizon. *Sigillaria*, so rare in the Lower Carboniferous rocks, is extremely abundant in the upper division, and particularly in the middle Coal-measures. In short, Mr. Kidston concludes that the floras of the two main divisions of the Carboniferous system, though belonging to the same types, are absolutely distinct in species, and in the relative importance of the genera.

By means of the fossil plants Mr. Kidston correlates the Coal-measures of Scotland underlying the red sandstones with the lower division of the Coal-measures of England, and the overlying red sandstones of Fife with the middle division of the English Coal-measures.

It is remarkable that the evidence supplied by the fossil fishes has led Dr. Traquair independently to a similar conclusion. He holds that fossil ichthyology proves the existence of only two great life-zones in the Carboniferous rocks of Central Scotland—an upper and a lower—the boundary line between the two being drawn at the base of the Millstone Grit. The Scottish Carboniferous rocks, being mostly estuarine, give an opportunity of comparing the estuarine fishes of both divisions. He finds the Coal-measure fishes of Scotland to be the same as those in the English Coal-measures, while those occurring below the

[1] "On the Various Divisions of British Carboniferous Rocks as determined by their Fossil Flora," *Proc.* Roy. Phys. Soc. Edin., vol. xii. p. 183 1893).

Millstone Grit in Scotland are mostly different in species, and often, too, in genera, from the forms above that horizon.

Of special interest as bearing on the former extension of this system in Scotland is the discovery made by Prof. Judd (*Quart. Journ. Geol. Soc.*, vol. xxxiv. p. 685) in 1877 of a patch of Carboniferous sandstones and shales, with well-preserved plant remains in Morven. Another small outlier of this formation has recently been found in the Pass of Brander by the Geological Survey ("Summary of Progress, Geological Survey," 1898, p. 129).

The reptiles from the Elgin sandstones, recently described by Mr. E. T. Newton (*Phil. Trans.*, vol. clxxxiv. 1893, p. 431); *ibid.*, vol. clxxxv., 1894, p. 573), add fresh interest to the study of these rocks. The structural relations of these sandstones have been fully treated by Prof. Judd in his great paper on the Secondary Rocks on the east of Scotland (*Quart. Journ. Geol. Soc.*, vol. xxix. p. 98), and again in his presidential address to this Section at Aberdeen (*Rep. Brit. Assoc.* for 1885, p. 994), who confirmed Huxley's well-known correlation of these beds with the Trias. The Dicynodont skull, identified by Prof. Judd and Dr. Traquair at the Aberdeen meeting of the British Association in 1885, and other remains found in the reptilian sandstones in Cutties Hillock Quarry, where they rest on Upper Old Red Sandstone with *Holoptychius*, have been described by Mr. Newton. He confirmed their affinity with Dicynodonts, though they were referred to the genera *Gordonia* and *Geikia*. But the most remarkable specimen was the skull named by Mr. Newton *Elginia mirabilis*. This extraordinary creature, with a pair of horns projecting like those of a short-horned ox, and with smaller spines and bosses, numbering thirty-nine, is related to the great *Pareiasaurus* from the Karoo beds of South Africa. Two other reptiles are described by Mr. Newton from this quarry, namely, a small crocodile-like animal, *Erpetosuchus Granti*—apparently nearly allied to *Stagonolepis*—and *Ornithosuchus Woodwardi*, which is probably a small Dinosaurian.

Mr. Newton has raised an interesting point in connection with his researches. He calls attention to the fact that the reptilian remains from the Cutties Hillock Quarry differ from those found at other localities in the Elgin district. For example, the Lossiemouth sandstones have yielded *Stagonolepis*, *Hyperodapedon* and *Telerpeton*; and the Cutties Hillock sandstones, the Dicynodonts (*Gordonia* and *Geikia*), the horned reptile (*Elginia*), the small crocodile-like *Erpetosuchus*, and the little Dinosaurian *Ornithosuchus*. Does this distribution indicate different stratigraphical horizons? is virtually the point raised by Mr. Newton. In connection with this inquiry he cites the evidence obtained in other countries. Thus, in the Gondwana beds of India, the series of reptiles similar to those of Elgin occur at different localities and on different stratigraphical horizons; *Dicynodonts* and *Labyrinthodonts* being found in the lower Panchet rocks, while *Hyperodapedon* and *Parasuchus* (allied to *Stagonolepis*) are met with in the higher Kota-Maleri beds. Again in the Karoo beds of South Africa the *Dicynodonts* and the great *Pareiasaurus*—the latter being the nearest known ally of the horned reptile (*Elginia mirabilis*) from Cutties Hillock, Elgin—occur low down in that formation. Further light is thrown on the question by the interesting discoveries of Amalitzky in Northern Russia, where a number of reptilian remains have been found closely allied to *Pareiasaurus*, *Elginia* and *Dicynodon*, in beds, which are referred to the Permian formation and accompanied by plants and mollusca which seemingly confirm this reference.[1]

In view of these foreign discoveries Mr. Newton concludes that the Elgin sandstones may probably represent more than one reptilian horizon, and that we are confronted with the possibility of their being of Permian age.

The difficulty of drawing a boundary line between the Trias and the Upper Old Red Sandstone of Elgin, which impressed the mind of the late Dr. Gordon, has had to be faced elsewhere in Scotland. In Arran, my colleague, Mr. Gunn, has shown that the Trias there rests on Upper Old Red Sandstone, both formations having a similar inclination. Even he, with his ripe experience, has had great difficulty in drawing a boundary between them on the west side of the island; but when the base line of the Trias is traced eastwards to Brodick it passes transgressively on to Carboniferous rocks.

Of special importance is the recent discovery in Arran of the fossils of the *Avicula contorta* zone ("Summary of Progress, Geological Survey, 1899," p. 133) by Mr. Macconochie, of the Geological Survey, to whose skill as a fossil collector Scottish geology owes much. With these occur Lower Liassic fossils, in sediments which are not now found in place in the island. These fossiliferous patches are associated with fragmental volcanic materials filling a great vent, the age of which will be referred to presently. This discovery has fixed the Triassic age of the red sandstones and marls in the south of Arran. The detailed mapping of the island by Mr. Gunn has demonstrated that the Triassic sandstones rest partly on the Old Red Sandstone, partly on the Carboniferous Limestone Series and partly on the Coal-measures.

In 1878 appeared the third of Prof. Judd's great papers on the Secondary Rocks of Scotland, wherein he unravelled the history of these strata as developed in the east of Scotland and in the West Highlands. His admirable researches, in continuation of the work done by Bryce, Tate and others embraced the identification of the life-zones, their correlation with those of other regions, the history of the physical conditions which prevailed in Scotland during Mesozoic time, and the working out of the structural relations of the strata (*Quart. Journ. Geol. Soc.*, vol. xxix. p. 97, vol. xxxiv. p. 660). He showed that their preservation on the east of Scotland was due to the existence of great faults, and those in the West Highlands to the copious outpouring of the Tertiary lavas. He was the first to detect the occurrence of Cretaceous rocks in the West Highlands, and to show the marked unconformability which separates them from the Jurassic strata. His main life-zones and his main conclusions regarding the Secondary Rocks of Scotland have so far been confirmed by the detailed mapping of the Geological Survey. An interesting addition to our knowledge of these rocks was made by my colleague, Mr. Woodward, in the course of his field work, who found the oolitic iron ore in the Middle Lias of Raasay, the position of which corresponds approximately with that of the Cleveland ironstone (*Geol. Mag.*, December 3, vol. x. p. 493 (1893).

The extensive plateau of Tertiary volcanic rocks in the Inner Hebrides has been a favourite field of research ever since the time of Macculloch, the great pioneer in West Highland geology. During the period under review much work has been done in that domain. According to Prof. Judd, that region contains the relics of five great extinct volcanoes and several minor cones, indicating three periods of igneous activity. The first was characterised by the discharge of acid lavas and ashes, the molten material consolidating down below as granite; the second by the outburst of basic lavas, now forming the basaltic plateau, connected with deep-seated masses that appear now as gabbro and dolerite; the third by the appearance of sporadic cones, from which issued minor streams of lava (*Quart. Journ. Geol. Soc.*, vol. xxx. p. 220).

In 1888 Sir A. Geikie communicated his elaborate monograph on the history of Tertiary volcanic action in Britain to the Royal Society of Edinburgh (*Trans.* Roy. Soc. Edin., vol. xxxv., part 2, p. 23), which has been incorporated, with fuller details, in his recent work on "The Ancient Volcanoes of Great Britain." His main conclusions may thus be briefly stated: (1) The great basaltic plateaux did not emanate from central volcanoes, but are probably due to fissure eruptions; (2) the basaltic lavas were subsequently pierced by laccolitic masses of gabbro, which produced a certain amount of contact alteration on the previously erupted lavas; (3) the protrusion of masses of granophyre and other acid materials by means of which the basic rocks were disrupted.

During the last six years Mr. Harker has been engaged in mapping the central part of the isle of Skye, and in the petrographical study of the rocks, the results of which have been summarised in the annual reports of the Geological Survey. As regards the basaltic lavas, he finds that while they have been of vast extent the individual flows have been of feeble volume, and show no evident relation to definite centres of eruption. There were two local episodes, however, which took the form of central eruptions: one represented by a number of explosive outbursts at certain points; the other, in the basalt succession, gave rise to rhyolitic rocks.

Mr. Harker further finds that the succeeding plutonic phase of activity, confined in Skye to what is now the central mountain tract, is represented by three groups of plutonic intrusions, in the following order: peridotites, gabbros and granites. The metamorphism set up in the basaltic lavas near the large plutonic masses presents points of interest, especially the

[1] Y. Amalitzky, "Sur les fouilles de 1899 de débris de vertébrés dans les dépôts Permiens de la Russie du nord." (Varsovie, 1900.)

widespread formation of new lime-soda-felspars from the zeolites in the lavas.

After the intrusion of the granite of the Red Hills, Mr. Harker finds that igneous activity took the form of intrusions of smaller volume, but in some cases of wide distribution. The great group of dolerite sills belongs to this period. An enormous number of acid and basic dykes followed, of several distinct epochs. A set of minor basic intrusions of quite late date is found in the gabbro district of the Cuillins, the most interesting of which takes the form of sheets of dolerite, parallel at any given locality, but always dipping towards the centre of the gabbro area. Mr. Harker considers that this remarkable system of injections presents a new problem in the mechanics of igneous intrusion. The latest phase of vulcanicity in the Cuillin district is a radial group of peridotite dykes. As regards the local group of rock in Central Skye Mr. Harker finds that the order of increasing acidity which ruled in the plutonic phase was reversed for the minor intrusions which followed.

In connection with the great development of volcanic activity in the West of Scotland in Tertiary time reference must be made to the remarkable volcanic vent in Arran the recognition of which is due to the suggestion of my friend Mr. Peach. This volcanic centre covers an area of about eight square miles, and lies to the south of the granite area of the island (*Quart. Journ. Geol. Soc.*, vol. lvii. p. 226 (1901). The vent is now filled with volcanic agglomerate and large masses of sedimentary material, some of which have yielded the Rhætic and Lower Lias fossils already referred to, the whole being pierced by acid and basic igneous rocks. One of the interesting features connected with it is the occurrence of fragments of limestone with the agglomerate, which has yielded fossils of the age of the chalk, thus proving that the vent is post-Cretaceous. There is thus strong evidence for referring the granite mass in the north of the island and most of the intrusive, acid, and basic igneous rocks to the Tertiary period. It furnishes remarkable proof of the suggestion of the Tertiary age of the Arran granite made by Sir A. Geikie in 1873 (*Trans.* Geol. Soc. Edin., vol. ii. p. 305). The story unfolded by this discovery is like a geological romance. The former extension of Rhætic and Lower Lias strata and of the chalk in the basin of the Clyde, and the evidence of extensive denudation in the south of Scotland, appeal vividly to the imagination.

This outline of the researches in the solid geology of Scotland would be incomplete without reference to the publication of Sir A. Geikie's great work on "The Ancient Volcanoes of Great Britain" (1897), in which the history is given of volcanic action in Scotland from the earliest geological periods down to Tertiary time. To investigators it has proved invaluable for reference. Nor can I omit to mention the new edition of his volume on "The Scenery of Scotland," wherein he depicts the evolution of the topography of the country with increasing force and fascination. In this domain it may be said of the author, "Nihil tetigit, quod non ornavit."

From the brief and imperfect sketch which I have tried to give of recent advances in the solid geology of Scotland it will be admitted that restless activity and progress have been characteristic of the last quarter of a century. But we may expect that the conclusions accepted now will be rigorously tested by our successors, probably in the light of new discoveries and with more perfect methods of research. It is well that it should be so, for thereby our branch of science advances. Meanwhile, as we look back on the phalanx of geologists that Scotland has produced—to Hutton and Hall, Murchison and Lyell, Hugh Miller and Fleming, Nicol and Ramsay—and reflect on the services which they rendered to geology, we may hope that this record of progress may prove a fitting sequel to the labours of these illustrious men.

SECTION G.

MECHANICS.

OPENING ADDRESS BY COLONEL R. E. CROMPTON, M.INST.C.E., PRESIDENT OF THE SECTION.

AT this the first meeting of the British Association of the new century I wish to lay before you some of the interesting problems presented by recent developments in means of locomotion on land which demand the best thoughts, not only of our engineers, but of everyone interested in the improvement in means of travelling and in the more rapid transit of goods.

During the seventy years which have passed since the introduction of railways in almost every country, passenger and goods traffic has developed itself to such an extent that almost everyone is interested in these questions; and of late years our attention has not been confined to railways only, but, owing to the invention of the cycle and motor-car, has also been directed to travel on our road-ways, which during the first fifty years of the railway era had somewhat fallen into disuse. I am not able, being limited to the length of this address, to deal with many of the interesting questions affecting our long-distance railways other than by referring to the probable early introduction of railways of a new type intended to attain a speed of 120 miles per hour and worked by electrical power. The railway race to Scotland of a few years back attracted the attention of the managers of American and Continental railways to railway speed questions, and we have seen during the last few years so great improvement in the speed of the trains and the comfort of the passengers in these countries that it appears that England has already been beaten in the matter of extreme railway speed, although it is probable that our railways still provide a larger number of rapid trains than either the American, German, or French do. But whether it be in England or in the countries I have mentioned, it appears that after all the speed limit of railways of the present system of construction is reached at about sixty-five or seventy miles per hour. Higher speed on level runs has undoubtedly been recorded, but it is not probable that anything greatly in excess of seventy miles per hour will be reached until our railway managers initiate an entirely new system of construction. The high-speed service that is now in contemplation, not only in England but in America and Germany, intends to attain speeds of more than one hundred miles per hour by providing electrical means of haulage sufficient to propel light trains consisting of one, or, at the most, a few cars; and in order to render this service successful to run these light trains at short intervals of time, so in effecting this high speed the railways will give a service which more nearly resembles the tramway service than our present system of heavy express trains at infrequent intervals. This high-speed service of light trains at frequent intervals is well suited to electrical haulage, as it works generating machinery situated at fixed points to the best advantage and enables the best return to be obtained from the necessarily heavy capital cost of copper in the conductors which transmit the energy along the length of the line, as it is evident that if the speed be sufficient to ensure that each section of the line only carries one running train, the costs of the conductors will be in proportion to the weight of that train.

Great advantages have already been made in adapting electrical traction to long lengths of railways. The work already done by Brown Boveri, of Baden, in Switzerland, at first on the mountain railways and afterwards on the Burghdorf-Thun full-gauge line, the experimental work of Ganz and Co., of Buda-Pesth, and of Siemens and Halske at Charlottenburg, have already shown that the power problems are nearly all of them solved, so that we may feel confident that electrical engineers will very shortly surmount any power difficulties that still remain. But this high-speed railways problem at present presents certain unknown factors which can only be satisfactorily determined by the actual testing and working the lines when carrying passengers. I refer to those which deal with the increased oscillation, vibration, and noise to be expected from the extreme speeds. These matters must be met so as to give sufficient comfort and protection to the passengers, for if passengers are rendered uncomfortable by the extreme speed the service can never become popular, and on this last question depends the most important question of all, viz. the extent to which the travelling public are likely to make use of a high-speed railway service. In attempting to forecast this matter, although we meet many business men who think it would be an undoubted advantage if the journeys between important business centres occupied half the time they do at present, in the United Kingdom there are only a few journeys of sufficient length to make saving of time of great importance, but the case is far different in America and on the Continent, where the business centres are much further apart than they are here. I, as an English engineer, foresee that this topographical question will cause our English engineers to be at a disadvantage as compared with American and Continental ones, for it appears likely that the number and mileage of high-speed railways is likely to be far greater in America and on the Continent than in the United Kingdom. Before I entirely leave the subject of very high-speed railways, a rather curious speculation presents itself to us: this is whether the need for rapid communication between town and town may not eventually be supplied by high-speed motor-cars on roads specially prepared for them. Mr. Wells in his interesting forecast in the *Fortnightly Review* seems to think that the time is not far distant when all passenger traffic will be carried on special roads on motor-cars. That the advantages of carrying your family and loading up your belongings at your own door, in your own or a hired car, and transporting them without any change or handling of your baggage right up to the point where your journey ends, will be so great that even for comparative long journeys travellers will prefer it to the railway, and that our railways will eventually be relegated to carrying minerals and heavy goods. But, without going so far as Mr. Wells, it does seem probable that if only a few passengers require to travel between two business centres such as Manchester and Liverpool, and to occupy only half the time from door to door at present taken by the railway and the two terminal cab rides, it might be better to provide one of Mr. Wells' improved roads on which private owners could run their own cars, paying toll for the road, and on which a public service of cars would provide for those who did not own cars themselves.

I now propose to deal at somewhat greater length with what I think is a most important problem in locomotion, viz. that caused by the congestion of street traffic in our towns and by the undoubted difficulties which exist in carrying our workers to and from their homes in the country to their places of employment in our towns. A large proportion of the workers who during the latter half of the last century lived and worked in the country are now working in towns, although some of them still live outside in order to obtain the advantages of lower rents and of a healthier life for their families, and this last class is likely to increase largely. Those who have been responsible for the enlarging and improvements of our towns have done so much to make town life preferable to country life that the country is gradually being depopulated. The results we see in the increasing difficulties which the town authorities find in dealing with the water and sewerage questions, and in the increasing mass of vehicular street traffic, which makes some of our cities veritable pandemoniums. Luckily it seems that we are likely through the skill and energy of our engineers to meet these difficulties in more than one way. The cycle, which commenced as an amusement and went on as a fashionable craze, has now settled down into being the poor man's horse. The number of our working population that use the cycle for going to and from their work is already very large and is steadily increasing, and their use of the roads must be considered. Then came the motor-car, developed in France to such an amazing extent, and which seems now likely to be developed to an equal extent in this country. After many years of objecting to the use of the overhead trolley system, our town authorities seem now to have determined that the only way of relieving street traffic is by an enormous development of electrical tramways, and on all sides we find the large towns rivalling one another in the extent of the tramway systems which they have either acquired or are laying down for themselves. It seems opportune now to point out that a great deal of mischief may accrue by this indiscriminate use of tramways, and for those who are considering these matters I bring forward a few facts which are worthy of notice. Of course, in new countries, or in new towns in old countries, where the roads are rough and bad, anything in the nature of a tramway using rails is an improvement on a roadway; but when we are dealing with cities which already possess well laid out and well paved streets on which all kinds of wheel traffic can be carried on with a minimum of rolling resistance, it seems wrong from an engineering point of view to break up the surface of these streets for the purpose of laying tramways, and for the following important reasons: Traffic carried on a roadway by vehicles, whether horse-drawn or by cycle or motor-car, differs from traffic carried on rails chiefly in that the former vehicles possess an important power, viz. that of *overtaking*, which is not possessed by the latter, that is to say that vehicles on the plain road surface can overtake a stopping or a slower vehicle going in the same direction without interfering with other vehicles, whereas on rails the vehicles going one way must always remain in the same relation to one another, so that the speed of vehicles on rails must always be regulated by that of other vehicles going in the same direction. Street tramways, for instance, must stop to set down and take up passengers: this limits the speed average and the number of vehicles per mile of track, for if there be not sufficient intervals between the vehicles they would have to stop and start nearly simultaneously. Thus the carrying capacity of the best modern electrical tramway is limited by this want of overtaking power. I have made careful inquiry from those who have great experience in tramways not only in this country but in America and on the Continent, and I find that it is generally admitted that the maximum carrying capacity of an electrical tramway in one direction is 4000 passengers per hour carried past any given point. I find that a full-gauge suburban or metropolitan railway crowded to its fullest extent cannot carry more than 12,000 passengers per hour. Now most of us have often seen large crowds taken away from a point of attraction by omnibuses and horse-drawn vehicles, and have noticed that the crowded omnibuses almost touch one another and yet can go at a fair rate of speed. In this case at eight miles per hour speed 14,000 passengers can be carried from a given point per hour.

Up to the present a public motor-car service has not yet been installed of any magnitude to enable us to compare the carrying capacity of motor-cars with that of horse-drawn omnibuses, but owing to the reduced length of motor-cars compared with that of omnibuses, and on account of their greater speed and greater control, motor-cars can now be built to deal with great crowds at an even higher rate per hour than that noted above. It appears certain, therefore, that although the provision of electrical tramways is undoubtedly an economical means of carrying passengers, yet that these tramways cannot be laid in existing thoroughfares without considerably reducing the total road carrying capacity at times of heavy pressure of traffic, and as it appears likely that either for the daily transport of the workers to and from their homes to places of employment, or for taking great crowds out into the country for pleasure purposes, a motor-car service carried out on well-made roads will compete favourably with, and in many ways may be preferable to, tramway service.

It must be remembered that the laying of tram rails not only blocks ordinary traffic, but in our most crowded streets it introduces dangers to all wheeled vehicles not on rails, motor-cars, and cyclists by the skidding of the wheels when they cross the line of rails, and these dangers are daily causing, and are still likely to cause, very serious accidents.

The increased road and street traffic and the development of new means of road locomotion have made imperative some modification of our existing system of roadway administration. Cycles, motor-cars, electrical tramcars, have been invented and put on roads which are maintained and worked exactly as they were seventy years ago at the commencement of the railway era, when the population of the United Kingdom was half its present figure, and that of the large towns one-tenth of the present figure. During the 150 years previous to the railway era the ancient tracks were gradually improved into tolerably efficient roads for coach and wagon traffic, but after the introduction of railways there was a complete cessation of improvement, as for fifty years after the railways started the old roads were equal to the farmers' and local traffic which the railways left for them; but for the last twenty years the roads near to the great towns have been inadequate, and now that the cyclist and motor-carist travel over the whole of the roads of the country the neglect of our ancient roadway system is very apparent.

Although the urban populations have so greatly increased, the old coaching roads are still the only ones that exist; no main roads parallel to the old ones or alternative to them have ever been made. Towns which are now joined by railways grew out of small rows of houses built facing the main road; in fact, in many cases the road made the town. During the early part of the railway era, when the roads were so little used from coaching falling into disuse, encroachments on the roadway took place in and near the towns, such roads being now actually narrower and less suitable for traffic than in the coaching days: so that these towns which owe their existence to these roadways now put every impediment and hindrance to their use by the travelling public. What is needed is that towns situated on our main through roads should provide alternative routes, so that through travellers could, if they desired, avoid the crowded streets of the town. One method of providing such relief roads would be by by-laws providing that all building estates should set aside land for main roads. The building estates which are developed around our great towns never provide a road which can be used as a main line of thoroughfare, although by their very act of building additional houses they cause additional congestion to the main roads. They lay out their roads to obtain quiet for those who live on the estate, and take every possible means to prevent their estate roads from taking a share of the main thoroughfare traffic.

Parliament must take in hand an improved administration of our highways by a comprehensive scheme. Far too many ancient main lines of thoroughfare, already too narrow for the traffic which is on them, are being blocked by having tramways laid on them; these cause the development of building estates, which throw additional traffic on to these thoroughfares. Apart from the roads themselves, the complicated conditions of street and road traffic demand careful regulation. Street traffic should be carried so far as possible by lines of vehicles driven as nearly parallel to one another as possible. The rule of the road, as it is called, and which is embodied in an Act of Parliament, 5 and 6 of William IV., which is commonly called the Highways Act, says that every vehicle is to keep as close as possible to the left, or near side of the road, except when overtaking another vehicle going in the same direction, and then it is to keep to the off side of the overtaken vehicle as closely as possible. As a matter of fact, everybody knows that this rule is habitually neglected by drivers who, whenever they get a chance, drive down the centre of the road, so that others who overtake them dare not do so on the wrong or near side, but must pass out far to the off side of the road, and consequently interfere with the traffic coming in the opposite direction. This neglect of the rule of the road causes a great waste of space immediately behind every vehicle, and is one of the chief causes of the limited carrying capacity of the streets in cities where the police do not attend to this important matter. It can be remedied by the existing police regulations being adhered to and insisted on by fixed-point constables, or by constables moving about on motor-cars or bicycles. Slow moving and frequently stopping vehicles are another cause of congested traffic. A great deal might be done by arranging that during certain hours much of the slower moving traffic is shunted into alternative routes, so as to be kept by itself. An increase in the speed of the street traffic is desirable; for the faster the vehicles travel the less the street is occupied by them. Motor-cars can safely travel at sixteen miles an hour, and, therefore, need only take half the time and occupy only half the street surface that an omnibus does when travelling at eight miles per hour. Such high speeds as these, which are desirable and perfectly safe for motor cars, cannot, however, be obtained unless some regulations are made as to the use of the roadways by foot passengers. There is no rule of the road for foot passengers—they pass one another on the footpath, or vehicles in the roadway, just as they please. No driver of a vehicle in the road who sees a foot passenger stepping into the roadway can ever tell with certainty what his movements will be. It will be no hardship to foot passengers to insist on their movements being regulated.

Much has been recently said and written on the subject of motor-cars and motor-wagons. It is generally admitted that there will be considerable scope for engineering skill and capital in their improvement and construction. It is by no means an easy problem to put into the hands of the public such a complicated piece of mechanism as a self-propelled carriage which has in most cases to be managed and driven by men who have had no special mechanical training. Motor-cars to be universally successful must be made so as to reduce to a minimum the liability to break down; repairs must be limited to the replacement of worn or damaged parts by other parts, which must be supplied by the manufacturers so that they can be readily put in by the unskilled users. That this can be done is shown by the success and universal use of typewriters, sewing machines, and bicycles: all of these are really complicated pieces of mechanism, but which are now in such general use and in everyone's hands. In these cases, however, the organised manufacture of machines with thoroughly interchangeable parts, or components as it is the fashion to call them, has only been developed after the type of machine had settled down, and this up to the present cannot be said of the motor-car or motor-wagon. Up to the present the development of these cars has gone on on several lines. The development in France, which so far has led the world, has been principally in the direction of the use of light motors driven by petrol spirit. Again to France we owe the flash boiler of Serpollet, which assists the use of steam engines for this purpose.

At first sight steam, with the complications of boiler, engine, and condenser, does not appear likely to compete favourably with the simpler spirit motor, but for heavier vehicles, where steady heavy pulling power is of importance, up to the present no internal combustion motor has competed with it. The Americans, with their usual skill and power of rapidly organising a new manufacture, have already turned out a very large number of steam-driven motor-cars, which are so largely in use in unskilled hands that it shows that they have already solved the problem to some extent.

The directions in which the two classes of motors require further development are, for the internal combustion motors, the satisfactory and inodorous use of the heavier oils, and in this perhaps Herr Diesel may help us with his wonderfully economical motor improvements in the clutch mechanism, for with all internal combustion engines up to the present it has been found impossible to start the motor when coupled to the driving-wheels of the car; and in the case of the steam motor the simplification of the boiler, the boiler feed mechanism, the inodorous and noiseless burning of heavy oils as fuel, improved condensers, methods of lubricating the pistons and valves so as to avoid oil passing back to the boiler with the condensed water, and the rendering of all processes of boiler feed and fuel feed mechanism completely automatic so as not to require the attention of the driver. On points common to both classes, although much has been done, further improvement is required in the methods of transmitting the power from the motor to the driving-wheels. In the case of the steam cars, where this has been done by single reduction, using chain, pinion, and sprockets, very efficient and noiseless transmission has already been obtained, but up to the present in most of the internal combustion engines where more than two cylinders have to be employed, it has been found necessary to arrange the crank shaft of the motor at right angles to the axle of the driving-wheels, so that part of the transmission having to be through bevel gear, this part has up to the present always been noisy. In the providing of noiseless and efficient chain driving, the manufacturer of cars has gained greatly by the high degree of perfection to which these chains had already attained for bicycle work.

The recent great road races which have taken place in France and elsewhere have shown that the motor-car can be driven safely at a very high speed, already reaching in some cases seventy miles an hour; but to render this capacity for high speed useful, not only must special roads be provided on which these high-speed cars can travel without danger to others and with least slip and wear and tear of tyres, but a great deal requires to be done in the improvement of the pneumatic tyres, which at present get excessively hot, and therefore damaged by these high-speed runs. At these high speeds the mechanical work done on the material of which the outer covers of pneumatic tyres are composed is excessively high. It can probably be reduced by increasing the diameter of the wheels, but, of course, at the cost of increased weight and, to some extent, of stability, for the side strains on the wheels of these cars when swinging round curves of sharp radius are very great.

Another direction in which mechanical invention is required for the wheels of motor cars and wagons is a shoeing or protection of hard material of easily renewable character which can be firmly and safely attached to the outside of the tyre covers to take the wear and cutting action caused by the driving strain and by the action of the breaks on sudden stops.

The late R. W. Thomson, of Edinburgh, made good progress some thirty years ago in providing steel shoeing for the solid rubber tyres he then used, and the problems of providing the same for pneumatic tyres ought to be no harder than those he then successfully encountered.

One of the topics which has been most strongly discussed during the last year has been the position which this country holds relatively to other countries as regards its commercial supremacy in engineering matters. A few years back we were undoubtedly ahead of the world in most branches of mechanical engineering, but owing to the huge development of mechanical engineering in America and Germany, we are certainly being run very hard by these countries, and everyone is looking for means to help us to regain our old position. In endeavouring to learn from America we see that, although the workmen in that country receive higher wages than they do here, and although the cost of some of the materials is higher than it is here, their manufacturers manage to deliver engines, tools, and machinery of all classes of excellent quality at a price which appears to our manufacturers to be marvellously low. When we look into the matter we find that the chief difference between the manufacturer of America and the manufacturer at home is that, whether it be steam-engines, tools, agricultural machinery, or electrical machinery, the American invariably manufactures goods in large quantities to standard patterns, whereas we rarely do so here, at any rate to the same extent. Where we turn out articles by the dozen the American turns them out by the hundred. This difference in the extent to which an article is reduplicated is caused by the Americans having realised to a far greater extent than we have the advantage of standardisation of types of machinery. They have felt this so strongly that we find in America that work is far more specialised than it is here, so that a manufacturer as a rule provides himself with a complete outfit of machinery to turn out large numbers of one article. He lavishes his expenditure on special machinery to produce every part sufficiently accurate to dimension to secure thorough interchangeability; consequently the cost of erecting or assembling the parts is far less than it is here. One reason why the American manufacturer has been able to impose on his purchasing public his own standard types, whereas we have not been able to do so, is that very rarely in America does a consulting engineer come between the manufacturer and the user, whereas here it is the fashion for the majority of purchasers of machinery to engage a consulting engineer to specify and inspect any machinery of importance. By this I do not impute any blame to our consulting engineer; he considers the requirements of his client, and insists that they are to be adhered to as closely as possible; to him the facility of the production of articles in large quantities is of no moment. In America it seems to be understood by the purchaser that it is a distinct advantage to everyone concerned, both manufacturer and purchaser, that the purchaser should to some extent give way and modify his requirements so as to conform with the standard patterns turned out by the manufacturer. Although manufacturers all hope for this simplification of patterns, yet, for the reasons I have given, it will be some time before their hope is realised. But on other matters it is quite possible for manufacturers to combine, so as to obtain some standardisation of parts which they manufacture which will reduce costs and be of advantage to everyone concerned. Many years ago Sir Joseph Whitworth impressed on the world the importance in mechanical engineering of extreme accuracy, and of securing the accurate fit and interchangeability of parts by standard gauges. But in spite of his idea being so widely known and taught, how seldom it has been acted upon to the extent that it should be. We pride ourselves on having all our screws made of Whitworth standard, and yet how many of the standard bolts and nuts made by different makers fit one another? I myself have sat on a committee of this Association which was called together twenty years ago, with Sir Joseph Whitworth as a member of it, to fix on a screw gauge which would be a satisfactory continuation of the Whitworth screw gauge down to the smallest size of screw used by watchmakers.[1] It has taken all these years to carry out the logical outcome of Sir Joseph Whitworth's original idea, viz. the providing of standards to be deposited in care of a public authority to act as standard gauges of references. The complete interchangeability of parts which I have above referred to, and which is so desirable in modern machinery, can, of course, be obtained within the limits of one works by that works providing and maintaining its own standards to a sufficient degree of accuracy. But if the articles be such as watches or bicycles, motor-cars, &c., it is very desirable that all parts liable to require replacement should be made by all manufacturers to one standard of size, and in order that the gauges required for this purpose should all be exact copies of one another it is necessary that they should be referable to gauges deposited either with the Board of Trade or with some body specially fitted to verify them and maintain their accuracy.

Up to the present the Board of Trade has dealt with the simple standards of weight, capacity, and length, but in other countries National Standardising Laboratories have been provided, viz. by the Germans at their Reichsanstalt at Charlottenburg, and with the happiest results; here at last, through the exertion of the Council of the Royal Society, our Government has been moved to give a grant in aid and to cooperate with the Royal Society to establish a National Physical Laboratory for this country. About ten years ago Dr. Oliver Lodge gave the outlines of a scheme of work for such an institution. Later Sir Douglas Galton, in his Presidential Address to this Association, called attention to the good work done by the Germans and the crying need that existed for such an institution in this country. The matter has since progressed. A laboratory is already in existence, and will soon be at work, at Bushey House, Teddington; it is a large residence, which was once occupied by the late Duke of Clarence and afterwards by the Duc de Nemours. It will make an admirable laboratory, as it has large and lofty rooms and a vaulted basement in which work can be carried on where it is important to secure the observer against changes of temperature.

[1] A report of this committee will come before you during this meeting.

The aims of a National Physical Laboratory have been well put forward by Dr. Glazebrook in a recent lecture at the Royal Institution, in which he points out how little science has up to the present come to be regarded as a commercial factor in our commercial world. The position of manufacturers of all classes must be helped and improved by a well-considered series of investigations on the properties of materials, measurements of forces, and by the careful standardisation of and granting certificates to measuring apparatus of all classes. Until the question is fairly faced and studied, few manufacturers realise how helpless individual effort or individual investigations must be when compared with comprehensive and continuous investigations which can be carried on by a National Laboratory so as to deal with the whole of each subject completely and exhaustively, instead of each investigation being limited by the temporary need of each manufacturer or user.

As an example Dr. Glazebrook showed how much has been done at Jena and afterwards at the Reichsanstalt in the development of the manufacture of glass used in all classes of scientific apparatus. The German glass trade has benefited enormously from these investigations. The microscopic examination of metals, which was begun by Sorby in 1864, has been much worked at by individual investigators in this country, but its further development, which is probably of enormous importance to arts and manufactures, is clearly the duty of a National Laboratory. We owe much to the investigations of the Alloys Research Committee of the Institution of Mechanical Engineers; but, again, this is work for the National Laboratory. As regards the measurement of physical forces how little is accurately known of the laws governing air resistance and wind-pressures, and the means of measuring them. Who can formulate with any certainty a law for the air resistances likely to be met with at speeds in excess of eighty miles an hour, the importance of which I have already noticed?

I have already alluded to the verification, care, and maintenance of ordinary standard gauges of accuracy. In this electrical age the accuracy of electric standards is of supreme importance.

These are only a few of the directions in which we can foresee that the establishment of a National Physical Laboratory will be of the greatest use and assistance to our country in enabling it to hold its own in scientific and engineering matters with its energetic rivals. The work has been commenced on a small scale, but it is to be hoped that its usefulness will become at once so evident and appreciated that it will soon be developed so as to be worthy of our country.

NOTES.

AN expedition to Patagonia has been undertaken, under the auspices of the French Minister of Public Instruction, by M. A. Tournouër, whose purpose is to continue his study of the Tertiary mammals of South America.

THE last number received of the *Victorian Naturalist* states that, on July 19, Prof. Baldwin Spencer telegraphed from Alice Springs that his expedition had finished its work at Barrow Creek, where six weeks had been spent among the Kaitish and Ummatjera tribes. Much valuable information relating to tribal organisations, totemic systems, &c., had been collected, and a fine series of photographs of sacred ceremonies, types of natives, &c., secured. The next main camp was to be formed at Tennant's Creek, about 150 miles further north (latitude 19° 30′ S.). The members of the party were in excellent health, and well pleased with the results of their work.

A TELEGRAM from Berlin, through Reuter's agency, states that the Chinese astronomical instruments which the Germans carried off from Peking have now been placed in the orangery in Sans Souci Park. The instruments were packed in fifty-six cases, and weighed 26,000 kilogrammes. It is stated in the *Cologne Gazette* that the German Government authorised their purchase by the German Minister in Peking, after the offer of the Chinese Government to make the German Emperor a present of them had been declined.

THE governors of the Bristol General Hospital have been authorised by Sir William Henry Wills to draw on him up to 600*l.* for the provision of the Finsen apparatus for the treatment of lupus.

THE Philosophical Society of Glasgow will in future be known as the Royal Philosophical Society of Glasgow, the change taking place by the King's pleasure in respect of the near approach of the hundredth anniversary of the foundation of the Society.

A MISSION, consisting of three or four members, which will be under the direction of the Pasteur Institute, will start next month from France for the study of yellow fever. The sum of 100,000 francs has been voted by the Chamber of Deputies and the Senate towards the cost of the expedition. Operations will, if possible, be begun first in Brazil.

A SPECIAL COMMISSION to inquire into the subject of irrigation in India will meet in Simla in October under the presidency of Sir Colin Scott Moncrieff. The Commission, which will take evidence, examine proposed projects and formulate conclusions for the guidance of the Government, will visit the Punjab and the irrigation colonies in Sindh, Gujarat, the Deccan, Madras, the Central Provinces, and Upper India.

OWING to losses in the staff by death and retirement, the following appointments have been made on the Geological Survey of the United Kingdom. Dr. J. S. Flett has been selected to assist in the petrographical work of the Survey, Mr. J. Allen Howe and Mr. H. H. Thomas have been appointed geologists on the English staff, Mr. H. B. Muff on the Scottish staff, and Mr. W. B. Wright on the Irish staff.

REALISING, from the experience gained on the steamship *Lucania*, the value of the Marconi system of wireless telegraphy, the Cunard Company have decided to fit three more of their vessels with the same apparatus, viz. the *Campania*, the *Umbria* and the *Etruria*.

ON Saturday last, at Dundee, a granite monument was unveiled to the memory of James Bowman Lindsay, an investigator and inventor whose experiments in connection with wireless telegraphy and other scientific advances fifty years ago ought not to be forgotten. Sir William Preece, in unveiling the monument, remarked that Bowman Lindsay was long before his time. He was a prophet who would compare with any prophet, for in 1834 he wrote that houses and towns would in a short time be lighted by electricity instead of gas, and heated by it instead of coal, and machinery would be worked by it instead of by steam. Sir William Preece recollected that while he was attached to the electrical department of the Electric Telegraphs Company there came from Dundee to London a gentleman with a proposal to dispense with wires and communicate across water. He was attached to Mr. Lindsay, and he made all the arrangements and conducted all the experiments to illustrate his system in London. Unfortunately there was really no necessity for the invention in those days. An invention to be of use must come at the proper time. There must be the want for it, otherwise it died. This accounted for the fact that the system of wireless telegraphy which was now associated with the name of Lindsay had been neglected.

THE *Electrician* states that a proposal has been submitted to the municipal authorities at Rouen, by the chief of the fire department, for the utilisation of the tramway trolley wires in connection with the extinguishing of fires. All the principal thoroughfares of the town are provided with electric tramways, and the proposal is that pumps capable of being electrically driven should be installed in a number of suitable positions on the tramway route, to be switched on to the trolley wires, so that the pumps may be used as occasion necessitates. The proposal is said to have been favourably received, and is now under the consideration of the authorities.

AN experimental test of Prof. Koch's theory that bovine tuberculosis is not transmissible to human beings is, says the *British Medical Journal*, about to be undertaken under the direction of the Chicago Health Department.

AN earthquake shock was experienced at Inverness at 1.25 on Wednesday morning, and a lighter shock was also felt at four o'clock. A rumbling sound was heard during the first disturbance, and buildings were shaken to such an extent that windows rattled, objects were thrown down, a few chimney-pots were toppled over, and bells were set ringing. The movement appeared to travel from south to north, and reports of its occurrence have been received from Ava, Invergordon, Kildary, Alness, Newtonmore, Pitlochry, Loch Errich, Aberdeen, and other places.

A RESEARCH INSTITUTE has been opened by the Government of the Malay States at Kuala Lumpur, near Singapore. The medical department is fully equipped for special and general pathological work for the scientific study of clinical medicine, experimental physiology, and bacteriology. The chemistry department is arranged for both organic and inorganic research. There are, in addition, a well-stocked photographic department, facilities for biological research, and a good library. To members of scientific commissions visiting the Malay Peninsula the Institute affords an excellent opportunity for working up and preparing collected material. The Institute is open to all workers irrespective of nationality.

THE council of the University of Bordeaux is, with the approval of the French Minister of Public Instruction, founding a diploma in colonial medicine. The diploma, says the *Lancet*, will be granted, after keeping of terms and passing an examination, (1) to doctors in medicine of a French university; (2) to doctors in medicine of foreign universities; and (3) to foreigners having a medical diploma which is recognised as equivalent to a French doctorate of medicine. The examination will comprise (*a*) a clinical examination in tropical pathology; (*b*) a practical examination in the demonstrations and manipulations which have been gone through during the terms; and (*c*) a *viva voce* examination upon the subjects taken up during the course of study.

A CENTRAL NEWS telegram from New York, dated September 13, states that Mrs. Peary, the wife of the Arctic explorer, has arrived at Sydney, Cape Breton, from the Polar regions. She reported that she met her husband in the vicinity of Cape Sabine on May 6. Lieutenant Peary informed her that he spent the winter of 1900 at Fort Conger. This summer he marched northward to Independence Bay, but was then compelled to return to Fort Conger, where he will again spend the winter. A Reuter telegram states that the explorer had rounded the northern limit of the Greenland archipelago, and had reached latitude 83° 50′. He proposes to resume his attempts to reach the Pole in the spring of 1902.

THE twenty-ninth annual meeting of the American Public Health Association was to be opened at Buffalo on Monday last, and to continue in session, under the presidency of Dr. Benjamin

Lee of Philadelphia, until Saturday of the present week. The following is a list of the subjects down for discussion:—The pollution of public water supplies; the disposal of refuse material; animal diseases and animal food; car sanitation; etiology of yellow fever; steamship and steamboat sanitation; relation of forestry to the public health; demography and statistics in their sanitary relation; cause, prevention and duration of infectious diseases; public health legislation; cause and prevention of infant mortality; disinfectants and disinfection; national leper homes; dangers to the public health from illuminating and fuel gas; transportation of diseased tissue by mail; the teaching of hygiene and granting of Diploma of Doctor of Public Health; school hygiene; sanitary aid societies. In the Section of Bacteriology and Chemistry the following questions will be discussed: On standard methods of water analysis; bacteriology of milk in its sanitary relations; variations of the colon bacillus in relation to public health; and exhibition of laboratory apparatus and appliances for teaching hygiene.

A MEETING of the Yorkshire Naturalists' Union will be held at Cadeby (near Doncaster) from Saturday to Thursday, September 21–26, for a fungus foray in the neighbourhood of Melton, Sprotborough and Warmsworth.

THE Government of Victoria, Australia, requiring a director of agriculture, the U.S. Department of Agriculture has recommended for the post Prof. B. T. Galloway, chief of the Bureau of Plant Industry, and Prof. W. M. Hays, agriculturist of the Minnesota Experiment Station.

THE Allahabad *Pioneer Mail* states that a scheme is under consideration by the trustees of the Indian Museum to abolish, on the ground of expense, the office of the trustees and to allow the work to be managed by the librarian of the Museum. The scheme was formally brought before a meeting of trustees recently to be cast into shape before being forwarded to the Government of India for sanction. It is understood that Mr. Risley, chairman of the trustees, has already approved of the more important points of the scheme in consultation with the Revenue and Agricultural Department of the Government of India.

DR. DAVID STARR JORDAN, president of Stanford University, Dr. Barton W. Evermann, ichthyologist of the U.S. Fish Commission, and Dr. W. H. Ashmead, of the U.S. National Museum, who spent the summer in the Hawaiian Islands investigating on behalf of the U.S. Government the fishes and other aquatic resources of the Islands, have now returned to the United States, says *Science*. The other members of the party will return during the present month, except Messrs. L. E. Goldsborough and George Sindo, who will go to Pago Pago in the Samoan Islands to make a collection of the fishes found there. The investigations are reported to have been very successful. The fishery methods, laws and statistics were carefully studied and large and important collections of the fishes were made. Upwards of 300 species were obtained, among which are many species new to science. A preliminary report will be shortly submitted to the Commissioner of Fish and Fisheries. The final report will not be made until more deep-sea work has been done about the islands.

THE Congress of the International Association for Testing Materials was held at Budapest on September 9 to 14, under the presidency of Prof. L. von Tetmajer, and was largely attended by engineers from all parts of the world. The delegates present included 4 from England, 41 from Austria, 3 from Belgium, 9 from Denmark, 2 from the United States, 36 from France, 152 from Hungary, 70 from Germany, 3 from Norway, 12 from Italy, 26 from Russia, 1 from Roumania, 3 from Spain, 1 from Servia, 10 from Switzerland and 5 from Sweden. After an inaugural presidential address and address of welcome from the Hungarian authorities, a representative of each country was elected an honorary president of the Congress, Mr. Bennett H. Brough being chosen for England and Prof. H. M. Howe for the United States. The other English and American members present were:—Sir William H. Bailey (Manchester), Mr. Bertram Blount (London), Dr. C. J. Renshaw (Ashton-on-Mersey) and Dr. R. Moldenke (New York). In addition to the various reports of committees dealing with technical problems, the following papers dealing with metals were read and discussed:—on the measurement of internal tension, by Mr. Mesnager (Paris); on the forms of carbon in iron, by Baron Jüptner (Leoben); on Brinell's researches, by Mr. A. Wahlberg (Stockholm); on the testing of metals by means of notched bars, by Mr. H. Le Chatelier (Paris), by Mr. G. Charpy (Paris) and by Prof. Belelubsky (St. Petersburg); on micrographical researches on the deformation of metals, by Mr. F. Osmond (Paris); on metallography, by Mr. E. Heyn (Charlottenburg); on the testing of railway material, by Mr. E. Vanderheym (Lyons); and on the international iron and steel laboratory, by Prof. H. Wedding (Berlin). Several papers dealing with stone and mortars were also read, and an interesting lecture on the iron industry of Hungary was delivered by Prof. Edvi-Illes (Budapest).

Two long and highly sensational letters, entitled "A New Record of Totemism" and "The Early Man and his Stones," by the Hon. Auberon Herbert, have appeared in the *Times* of the 3rd and 7th inst. respectively, describing what he believes to be an important discovery of worked flints. His view, in brief, is that very extensive gravel beds in south Hampshire are practically entirely composed of worked flints which have been carried to their present position by man and then rearranged by water. The age and mode of formation of the gravel beds is a matter for the geologists to determine, and there is little doubt as to what they will say about the origin of the gravels. Archæologists must decide on the question whether the specimens submitted to them by Mr. Herbert are natural forms or artifacts. Judging from the numerous instances of analogous finds the verdict will be against Mr. Herbert's hypothesis; but he may rest assured that if he produces his evidence it will receive due consideration from anthropological or archæological experts. Mr. Herbert sees in his specimens animal and other natural forms, and arrives at the conclusion that they were "totems." Totemism, however, has too long been a "blessed word," and the time has arrived when strong protest must be made against the misuse of the term. There are many animal and plant cults in the world, and totemism is one of them; indeed it is probable that what is described as totemism among one people may be different from what is called totemism elsewhere. Should this prove to be the case the term should be restricted to practices and beliefs which are undoubtedly similar to those of the Ojibway cult. It is entirely unwarrantable to speak of every animal cult as totemism; the elucidation of primitive beliefs is rendered more difficult, one might say it is made almost impossible, by such looseness of terminology. It is not going too far to assert that whatever the stones may be they can never be proved to be totems or representations of totems.

DR. CARL LUMHOLTZ, the Norwegian explorer, who for the past five years has been travelling in the hitherto unknown regions of North-Western Mexico for the American Museum of Natural History, lectured before the Geographical Society in Christiania on September 12 and gave a description of his life and travels among the wild Indian tribes of the Western Sierra Madre, and especially among the cave-dwellers, who still live in the same primitive way as their forefathers thousands of years ago. In order to study these interesting people he sent back the entire staff of his expedition and lived alone among them. At first the tribes objected to his taking up his abode in this way, but eventually he gained their confidence and was allowed to remain. He learnt their ways, their language and their songs, and joined in their dances. The Mexican Indians are monogamists, and lead, on the whole, a happy existence. They are very intellectual, and are, according to Dr. Lumholtz, a far superior race to their kinsmen in the United States and South America. Among many of the tribes he found a higher degree of morality than in civilised countries. Theft and many of the worst forms of disease are unknown among them. The land is held in common. Their principal food consists of Indian corn and beans. The large and interesting collection of native pottery and implements which have been brought away for the American Museum of Natural History, and the explorer's researches into the life, customs, religion, &c., of the natives, will, it is thought, throw a new light upon many hitherto unknown periods in the history and evolution of mankind.

WE have received a copy of the Meteorological Observations for the year 1900, taken at Rousdon Observatory, Devon, under the superintendence of the late Sir Cuthbert E. Peek, Bart. This valuable series of observations was commenced in 1883, as a station of the second order, and subsequently important additions have been made, including Robinson and Dines' anemometers. In addition to the usual observations, which have been regularly and carefully made, as in former years, by Mr. C. Grover, much useful experimental work has been carried on, including a comparison of rainfall at different heights and of records of different types of anemometers. A comparison of the weather experienced at the Observatory with that predicted for the district by the Meteorological Office has been made daily since 1883. The percentage of absolute success during the year 1900 amounted to 85, and shows a considerable improvement on some of the earlier years. In an appendix the average monthly and yearly meteorological results for the seventeen years 1884–1900 are given in English and French measures.

A SERIES of papers on the radiation from carbon is commenced by Mr. E. L. Nichols in the *Physical Review* for August. The object of the experiments is to measure the temperature of carbon rods rendered incandescent by the passage of an electric current, and to make spectrophotometric comparisons of the visible radiation from their surfaces with the corresponding wave-lengths in the spectrum of an acetylene flame.

A SIMPLE circular slide-rule is described by M. Pierre Weiss in the *Journal de Physique* for September. It possesses only a single graduated dial, the logarithmic scale going from 1 to 10 in 360°, but it has two needles, one pivoted inside the other, so that when the latter is revolved the former turns with it. In order to multiply a by b, one needle is placed opposite unity and the other opposite a. The needles are then revolved together until the first needle is opposite b, the second will then be opposite the reading corresponding to the product ab. To perform division or to find the fourth proportional to three given numbers by a single operation, the method is closely analogous to that with a slide-rule.

IN a recent issue of the *Proceedings* of the Philadelphia Academy, Dr. A. M. Reese describes the evolution of the nasal passages in the Florida alligator. In the same journal Mr. H. A. Pilsbry records a number of additions to the land-snail fauna of Japan.

THE following recently appeared in the *Daily Telegraph* :—"Experts in the British Museum are investigating an extensive discovery of sharks' teeth and the palates of other fish which has been made in Goldsworth Cutting, Woking, during the excavations for the widening of the London and South-Western main line. The teeth, which were found in large numbers in the greensand formation, about 35 feet below the subsoil, are in a state of splendid preservation, and the find is regarded as an unusually interesting one." The specimens are really of Tertiary age.

IN a series of "Notes from the Gatty Marine Laboratory, St. Andrews," published in the *Annals and Magazine of Natural History* for September, Prof. M'Intosh discusses the enormous destruction of ova and fry which occurs in certain shore fishes, such as the shanny, blenny, cottus and lump-sucker (the eggs of which were recently produced to the Royal Commission on Trawling as those of the haddock). With regard to food-fishes, Prof. M'Intosh takes a hopeful view, urging that they "are in no great danger of extinction by the operations of man. These fishes have a vast area of water, which is utilised not only for the migrations of the adults, but for the spread of the pelagic eggs, larvæ, post-larval forms and adolescents. Even were the inshore flat-fishes, for instance, to be reduced to such a degree that their capture would no longer be profitable, that fact would be their safeguard, for they would be left, amidst the most favourable surroundings, to augment their decimated ranks."

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, presented by Lieut. R. P. Crawley; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. L. H. Ellis; a Bosman's Potto (*Perodicticus potto*), an African Civet Cat (*Viverra civetta*) from West Africa, presented by Mr. H. W. L. Way; two Lapwings (*Vanellus vulgaris*), European, presented by Mr. L. J. Coussmaker; twenty Rhomb-marked Snakes (*Trimerorhinus rhombeatus*), twenty-two Crossed Snakes (*Psammophis crucifer*), seventeen Rufescent Snakes (*Leptodira hotamboeia*), seven Rough-keeled Snakes (*Dasypeltis scabra*), three Infernal Snakes (*Boodon infernalis*), a Lineated Snake (*Boodon lineatus*), a Smooth-bellied Snake (*Homalosoma lutrix*), an Oldham's Snake (*Chlorophis hoplogaster*) from South Africa, presented by Mr. W. A. Guthrie; eleven Tenrecs (*Centetes ecaudatus*) from Madagascar, a Barnard's Parrakeet (*Platycercus barnardi*), a Yellow-rumped Parrakeet (*Platycercus flaveolus*) from South Australia, a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, a Red-vented Parrot (*Pionus menstruus*), twelve Brazilian Tortoises (*Testudo tabulata*) from South America, three West Indian Agoutis (*Dasyprocta cristata*) from the West Indies, two Rollers (*Coracias garrulus*), European; two Grey Monitors (*Varanus griseus*) from North Africa, two Starred Tortoises (*Testudo elegans*), three Ceylonese Terrapins (*Nicoria trijuga*), a Bungoma River Turtle (*Emyda granosa*), five Bengal Monitors (*Varanus bengalensis*) from India, deposited; a Proteus (*Proteus anguinus*) from the Caves of Carniola, presented by Mr. G. Churchill.

OUR ASTRONOMICAL COLUMN.

DIAMETER OF MERCURY.—Prof. T. J. J. See has recently made a long series of determinations of the diameter of the planet Mercury, using the filar-micrometer on the 26-inch refractor of the U.S. Naval Observatory at Washington. Details of 145 observations are grouped in three series, extending over the period 1900 June 20–1901 June 11. The mean diameter deduced is

$$D = 5''{\cdot}8993 \pm 0''{\cdot}0080.$$
$$= 4277{\cdot}6 \text{ km.} \pm 5{\cdot}8 \text{ km.}$$

Special attention is drawn to the absence, even under the best conditions, of any markings which could be recognised with certainty.

There was no noticeable falling off in the brightness of the planet near the limb, so that there appears to be no evidence of any kind of atmospheric absorption on Mercury.

The paper concludes with a list of previous measures of the diameter, and a discussion of the reasons why heliometer and filar-micrometer measures of diameter do not always agree, the discrepancy being ascribed chiefly to the distortion produced by the division of the objective in the heliometer (*Astronomische Nachrichten*, Bd. 156, No. 3737).

PERIODICITY OF THE INEQUALITIES OF MERCURY.—In the *Bulletin de la Société Astronomique de France*, pp. 402–403, 1901, M. Souleyre gives some results of his investigations into the variation of the inequalities of the planet Mercury. The times of contact of the planet with the sun's disc have been reduced from the observations available during the period 1677–1894, and the residuals are found to have a probable relation to the sun-spot period, inasmuch as the errors are all *positive* at or near the years of sun-spot *maxima*, and *negative* about the times of sun-spot *minima*. A rather discordant value is found for 1894, but the error is very small for that year.

The mean error for years of maxima is about +6 seconds, and
,, ,, ,, minima ,, −9 ,,

EVIDENCE OF THE EXISTENCE OF AN ULTRA-NEPTUNIAN PLANET.—In a paper read before the Royal Society of Edinburgh (*Proc.* Roy. Soc. Edinburgh, vol. xxiii. pp. 370–374), Prof. G. Forbes outlines the observations and calculations which he considers indicate the probable existence of a planet beyond Neptune. The chief factor on which the discussion is based is the proposition enunciated by Prof. Newton in 1879, stating that *if the elliptic orbits of comets have been changed from parabolas by planetary perturbations*, then the aphelion position of the new orbit will most probably be that occupied at the time of change. Prof. Forbes in 1880 (*Observatory*, June 1880) found that seven comets had aphelia distances about equal to one hundred times the mean distance of the earth from the sun.

The present note then deals more particularly with the recent discovery of a remarkable confirmation of these original results. The comet of 1556 (possibly identical with that of 1264) was not detected in 1848, and the computations undertaken show that the longitude of the new planet in 1696 was 112°, and its distance about one hundred times the earth's mean distance. The number of comets affected by these observed perturbations is so large that the new planet is probably greater than Jupiter.

A minute examination of all the comets in Galle's Catalogue showed the author that no one of them represented the lost comet of 1556, and a further search has been made among those comets to which elliptic orbits have not yet been assigned. Of these comets 1844 iii. or 1843 ii. turn out to have aphelion longitudes near 115°. This position, he calculated, would be occupied by the hypothetical planet about 1705, and if the former comet (1844 iii.) should be the representative of the long lost comet 1556, the observed perturbations would all be as required by the theoretical deductions, viz. the node has retrograded considerably, the inclination greatly increased, and the longitude of perihelion advanced. The chief discrepancy is in the latitude of aphelion, which is smaller than would be expected. It thus appears that the long lost comet 1556 is represented by that of 1844 iii. perturbed by a planet considerably larger than Jupiter, situated at about one hundred times the mean distance of the earth from the sun, and whose longitude is about 181° in the present year 1901. A re-examination of the 1556 observations is in progress, in the hope of finding more definite information.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Sunderland Municipal Technical College, which has been erected at a cost of 27,000*l.*, was opened on Friday last.

THE new technical school at Liverpool, the foundation stone of which was laid on July 1, 1898, is now practically completed and will shortly be opened. The school will accommodate 1300 students. The rooms devoted to chemistry and navigation are already in use.

MR. W. J. POPE has been appointed professor of chemistry and head of the chemistry department at the new Municipal School of Technology at Manchester. He has been succeeded as head of the chemistry department of the Goldsmiths' Institute, New Cross, by Dr. A. Lapworth.
